Part 4
Milk

23
Dairy Products

Terri D. Boylston

Abstract: This chapter provides an overview of the biochemistry and processing of cultured dairy products. The role of lactic acid bacteria in developing cultured dairy products and coagulation of the milk proteins through either enzyme addition or acid production is emphasized. The biochemistry involved in the processing of natural and processed cheeses, butter, buttermilk, sour cream, yogurt, and acidophilus milk is discussed.

INTRODUCTION

Cultured dairy products were originally developed as a means to preserve milk through the production of lactic acid. However, these products are also recognized because of their desirable sensory characteristics and nutritional value. The term, cultured dairy products, is currently used to indicate that these products are prepared using lactic acid bacteria starter cultures and controlled fermentation. The lactic acid bacteria utilize the nutrients in the milk to support their growth. The production of lactic acid reduces the pH of these products to inhibit the growth of many pathogenic and spoilage microorganisms. In addition, the fermentation process develops a wide range of dairy products with a diversity of flavor and textural attributes, including cheese, yogurt, buttermilk, butter, acidophilus milk, and sour cream.

Chapters 24 and 25 provide detailed information on the biochemistry and processing of milk and milk products. This chapter will focus on the biochemistry and processing involved in the production of cultured dairy products. This chapter will include a general discussion of the biochemistry and processing of cultured dairy products, followed by a discussion of the processing of the individual dairy products.

BIOCHEMISTRY OF CULTURED DAIRY PRODUCTS

COMPOSITION OF MILK

The quality of the cultured dairy products is influenced by the composition and quality of the raw milk. Species, breed, nutritional status, health, and stage of lactation of the cow can have an impact on the fat, protein, and calcium content and overall composition and quality of the milk. On the average, cows' milk consists of 3.7% fat, 3.4% protein, 4.8% lactose, 0.7% ash, and has a pH of 6.6 (Fox et al. 2000). Good microbiological

quality of the raw milk is also essential to the production of safe, high-quality cultured dairy products.

The predominant sugar in milk is lactose, a disaccharide of glucose and galactose. The fermentation of lactose by lactic acid bacteria in cultured dairy products provides the flavor and textural attributes that are desirable in cultured dairy products.

The fat is present in the milk in the form of fat globules, which are surrounded by a polar milk fat globule membrane (MFGM). Triacylglycerols are the predominant lipid fraction in milk, accounting for 98% of the total lipids. Diacylglycerols, monoacylglycerols, fatty acids, phospholipids, and sterols account for the remaining lipid fraction. The phospholipids are integral components of the MFGM. Approximately 65% of the fatty acids in milk fat are saturated, including 26% palmitic acid and 15% stearic acid. A significant amount of short- and middle-chain fatty acids, including 3.3% butyric acid are present. These fatty acids and the breakdown products of these fatty acids are important contributors to the flavor of many cultured dairy products.

Two major classes of milk proteins are caseins and whey proteins. The caseins, which make up 80% of the total protein in cow milk, are insoluble at a pH of 4.6, but are stable to heating. The whey proteins remain soluble at pH 4.6 and are heat sensitive.

The casein micelles exist in milk as a colloidal dispersion, with a diameter ranging from 40 to 300 nm and containing approximately 10,000 casein molecules. The principal casein proteins, α_{s1}, α_{s2}, β, and κ, present in the ratio 40:10:35:12, vary in the number of phosphate residues, calcium-sensitivity, and hydrophobicity. Within the casein micelle, the more hydrophobic proteins, such as β-casein, are located on the interior of the micelle, while the more hydrophilic proteins, such as κ-casein, are located on the surface of the micelle. The carboxyl end of κ-casein is dominated by glutamic acid residues and glycoside groups. These hydrophilic carboxyl-ends are represented as "hairy" regions in the model of the casein micelle and promote the stability of the casein micelle in solution (Walstra and Jenness 1984). Calcium phosphate further facilitates the association of individual calcium-sensitive casein proteins (α_{s1}-, α_{s2}-, and β-casein), within the casein micelle. Hydrogen bonds and hydrophobic interactions also play a critical role in stabilizing the casein micelle. Processing treatments applied during the formation of cultured dairy products, such as the addition of acid or enzymes destabilize the casein micelle causing the casein proteins to precipitate (Lucey 2002).

The whey proteins consist of four major proteins, β-lactoglobulin (50%), α-lactalbumin (20%), blood serum albumin (10%), and immunoglobulins (10%). These proteins have a significant number of cysteine and cysteine residues and are able to form disulfide linkages with other proteins following heat treatment.

Fresh cow's milk is characterized as having a distinctive subtle flavor. Classes of volatile flavor compounds that have been shown to have the greatest impact on milk flavor include nitrogen heterocyclics, linolenic acid oxidation products, γ-lactones, phenolics and phytol derivatives; many of these compounds are found in foods of plant origin. Differences in the milk flavor from cows fed different diets have been attributed to concentration differences of these flavor compounds rather than the presence of different compounds (Friedrich and Acree 1998, Bendall 2001). Although these flavor compounds are not significant contributors to the characteristic flavors of cultured dairy products, they do contribute to the background flavors of these products (Urbach 1995).

LACTIC ACID BACTERIA

The lactic acid bacteria used in the development of cultured dairy products include *Streptococcus, Lactococcus, Leuconostoc*, and *Lactobacillus* genera. These bacteria are gram-positive bacteria and belong to either the *Streptococcaceae* or *Lactobacillaceae* families, depending on the morphology of the bacteria as cocci or rods, respectively. These bacteria also differ in their optimal temperature for growth, with 20–30°C the optimal temperature for mesophilic bacteria and 35–45°C the optimal temperature for thermophilic bacteria. Although the lactic acid bacteria are quite diverse in growth requirements, morphology, and physiology, they all have the ability to metabolize lactose to lactic acid and reduce the pH of the milk to produce specific cultured dairy products. The heat treatment the cultured dairy products receive following inoculation is one of the factors that influences the selection of lactic acid bacteria for specific cultured dairy products. Table 23.1 summarizes the growth characteristics of common lactic acid bacteria.

KEY PROCESSING STEPS IN CULTURED DAIRY PRODUCTS

Many of the processing steps important in the production of cultured dairy products are not unique to a specific product. Therefore, the following discussion will provide an overview of the key processing steps that are used in the production of several cultured dairy products. Specific processing treatments and concerns will be highlighted within the discussion of the processing of the specific cultured dairy products.

LACTIC ACID FERMENTATION

Lactic acid bacteria use the lactose in the milk to produce lactic acid and other important flavor compounds in the cultured dairy products. Many of these bacteria have lactase activity and hydrolyze lactose to its monosaccharide units, glucose and galactose, prior to further metabolism. The hydrolysis of lactose in most cultured dairy products is significant for individuals who are lactose intolerant, allowing them to consume dairy products without the undesirable effects of the inability to hydrolyze lactose.

The homofermentative lactic acid bacteria produce lactic acid from lactose according to the reaction

Lactose + 4ADP + 4H$_3$PO$_4$ → 4Lactic Acid + 4ATP + 3H$_2$O
The glucose and galactose molecules are metabolized through the glycolytic and tagatose pathways, respectively. Key steps in

the formation of lactic acid from the monosaccharides include the hydrolysis of the hexose diphosphates to glyceraldehyde-3-phosphate by aldolases, the formation of pyruvate from phosphoenolpyruvate by pyruvate kinase, and the reduction of pyruvate to lactate by lactate dehydrogenase. Heterofermentative lactic acid bacteria metabolize lactose to produce carbon dioxide, acetic acid, and ethanol, in addition to lactic acid according to the reaction

$$\text{Lactose} + 2H_3PO_4 + 2ADP \rightarrow 2\text{Lactic Acid} + 2\text{Ethanol}$$
$$+2CO_2 + 2ATP + H_2O$$
The heterofermentative lactic acid bacteria lack aldolases, therefore, the sugars are metabolized through 6-phosphogluconate pathway rather than the glycolytic pathway. In this pathway, glucose-6-phosphate is oxidized to 6-phosphogluconate, which is decarboxylated to a pentose-5-phosphate and carbon dioxide by phosphoketolase. The pentose-5-phosphate is converted to glyceraldehyde-3-phosphate, which enters the glycolytic pathway to form lactic acid and acetyl-phosphate, which is metabolized to acetaldehyde. The acetaldehyde is reduced to ethanol by alcohol

dehydrogenase. However, several bacteria, including *Lactococcus lactis* ssp. *lactis* biovar. *diacetylactis, Streptococcus thermophilus,* and *Lactobacillus delbrueckii* ssp. *bulgaricus* lack the dehydrogenase and accumulate acetaldehyde.

The production of acid by the lactic acid bacteria has a significant impact on the safety and quality of the cultured dairy products. The reduction in pH increases the shelf life and safety of the cultured dairy products through the inhibition of spoilage and pathogenic microorganisms. Acid production by these lactic acid bacteria is critical for the precipitation of the casein proteins in the formation of several cultured dairy products, such as yogurt, sour cream, and unripened cheeses. These bacteria may also contribute to the degradation of proteins and lipids through proteolytic and lipolytic reactions to further develop the unique texture and flavor characteristics of the cultured dairy products. These reactions are especially important in ripened cheeses. The selection of the appropriate type and level of starter cultures is imperative for the development of the appropriate flavor characteristics.

Metabolism of citrate by *Lactococcus, Leuconostoc,* and other lactic acid bacteria results in the formation of diacetyl

(2,3-butanedione), acetoin, and 2,3-butanediol, which are key volatile flavor compounds in cultured dairy products. Diacetyl is formed through the chemical oxidation of α-acetolactate. Diacetyl reductase (also referred to as acetoin reductase) catalyzes the irreversible reduction of diacetyl to acetoin and the reversible reduction of acetoin to butanediol in which NAD(P)H acts as the coenzyme (Hugenholtz 1993, Rattray et al. 2000, Østlie et al. 2003). Diacetyl contributes to the characteristic buttery flavor of many cultured dairy products. There is significant interest in adapting processing methods that will enhance the formation of diacetyl or decrease diacetyl reductase activity to maintain these desirable flavor characteristics (Rattray et al. 2000).

Many commercial dairy processors now use the direct vat inoculation (DVI) process for frozen or freeze-dried cultures (up to 10^{12} bacteria per gram of starter) in the processing of cultured dairy products. The use of DVI cultures allows the dairy processor to directly add the cultures to the milk and by-pass on-site culture preparation. This recent progress in the development of starter cultures has also increased phage resistance, minimized the formation of mutants which may alter the characteristics of the starter cultures, enhanced the ability to characterize the composition of the cultures, and improved the consistent quality of cultured dairy products. However, the DVI process is limited by the additional cost of these cultures, the dependence of the cheese plants on the starter suppliers for the selection and production of the starters, and the increased lag phase of these cultures in comparison to on-site culture preparation (Stanley 1998, Tamime and Robinson 1999a, Canteri 2000).

Coagulation of Milk Proteins

The production of lactic acid by lactic acid bacteria decreases the pH of the milk to cause coagulation of the casein. As the pH decreases to less than 5.3, colloidal calcium phosphate is solubilized from the casein micelle, causing the micelles to dissociate and the casein proteins to aggregate and precipitate at the isoelectric point of casein (pH 4.6). The resulting gel, which is somewhat fragile in nature, provides the structure for sour cream, yogurt, and acid-precipitated cheeses, such as cream cheese and cottage cheese (Lucey 2002).

The casein micelles are also susceptible to coagulation through enzymatic activity. Rennet, a mixture of chymosin and pepsin, obtained from calf stomach, is most commonly recognized as the enzyme for coagulation of casein. However, proteases from microorganisms and produced through recombinant DNA technologies have been successfully adapted as alternatives to calf rennet (Banks 1998). Chymosin, the major enzyme present in rennet, cleaves the peptide bond between Phe-105 and Met-106 of κ-casein, releasing the hydrophilic, charged casein macropeptide, while the *para*-κ-casein remains associated with the casein micelle. The loss of the charged macropeptide reduces the surface charge of the casein micelle and results in the aggregation of the casein micelles to form a gel network stabilized by hydrophobic interactions. Temperature influences both the rate of the enzymatic reaction and the aggregation of the casein proteins, with 40–42°C, the optimal temperature for casein coagulation. The use of rennet to hydrolyze the peptide bond and cause aggregation of the casein micelles is used in the manufacture of most ripened cheeses (Lucey 2002).

Homogenization

Milk fat globules have a tendency to coalesce and separate upon standing. Homogenization reduces the diameter of the fat globules from 1–10 μm to less than 2 μm and increases the total fat globule surface area. The physical change in the fat globule occurs through forcing the milk through a small orifice under high pressure. The decrease in the size of the milk fat globules reduces the tendency of the fat globules to aggregate during the gelation period. In addition, denaturation of the whey proteins and interactions of the whey proteins with casein or the fat globules can alter the physical and chemical properties of the milk proteins to result in a firmer gel with reduced syneresis (Tamime and Robinson 1999b, Fox et al. 2000). Milk to be used to process yogurt, cultured buttermilk, and unripened cheeses is commonly homogenized to improve the quality of the final product.

Pasteurization

The original cultured dairy products relied on the native microorganisms in the milk for the fermentation process. Current commercial methods for all cultured dairy products include a pasteurization treatment to kill the native microorganisms, followed by inoculation with starter cultures to produce the desired product. The heat process, which must be sufficient to inactivate alkaline phosphatase, also destroys many pathogenic and spoilage microorganisms, and enzymes that may have a negative impact on the quality of the finished products. The time-temperature treatments for the fluid milk pasteurization have been adapted for the milk to be used in the processing of cultured dairy products (62.8°C for 30 minutes or 71.1°C for 15 seconds). More severe heat treatments than characteristic of pasteurization causes denaturation of whey proteins and interactions between β-lactoglobulin and κ-casein. In cheeses, this interaction decreases the ability of chymosin to hydrolyze the casein molecule and initiate curd precipitation and formation.

Pasteurization has a significant effect of the flavor profile of the milk. Cultured dairy products produced from pasteurized milks tend to have less intense flavor characteristics due to the heat inactivation of the naturally occurring microorganisms and enzymes in the milk that contribute to flavor formation (Buchin et al. 1998). Lactones and heterocycles are also formed during the heat treatment of raw milk to contribute cooked flavors (Friedrich and Acree 1998).

Cooling

The processing of cultured dairy products relies on the metabolic activity of the starter cultures to contribute to acid formation and flavor and texture development. Once the desired pH or titratable acidity is reached for these products, the products are cooled to 5–10°C to slow the growth of the bacteria and limit further acid production and other biological reactions.

PROCESSING OF CULTURED DAIRY PRODUCTS

The following discussion highlights the unique processing steps that are involved in the production of cultured dairy products. These processing steps contribute to the unique flavor, texture, and overall sensory characteristics of these products.

CHEESE

Over 400 different varieties of cheese have been recognized throughout the world. The wide diversity in the flavor, texture, and appearance of these cheeses is attributed to differences in the milk source, starter cultures, ripening conditions, and chemical composition. Cheeses are frequently classified based on moisture content, method of precipitation of the cheese proteins, and the ripening process. Table 23.2 compares processing methods and composition of selected cheeses.

The coagulation of the casein proteins, separation of the curds from the whey, and ripening of the curd are the primary steps involved in the processing of cheese. The resulting product is a highly nutritious product in which the casein and fat from the milk are concentrated. The fat plays a critical role in the texture of the cheese by preventing the casein molecules from associating to form a tough structure. In general, most cheeses can be classified as natural or processed cheeses. The natural cheeses include ripened or unripened cheeses. The stages involved in processing these different types of cheeses and their unique characteristics will be discussed further.

Natural Cheeses

A simplified overview of the steps involved in processing fresh and ripened natural cheeses is presented in Figure 23.1. Fresh cheeses are consumed immediately after processing and are characterized as having a high moisture content and mild flavor. Most fresh cheeses are acid-coagulated cheeses, in which lactic acid produced by the starter cultures causes the precipitation of the caseins. The final pH of the acid-coagulated cheeses is 4.6. Rennet is primarily used for the coagulation of the casein proteins and curd formation in ripened cheeses. Starter cultures are added to produce acid and contribute enzymes for flavor and texture development during ripening. Ripened cheeses undergo a ripening period, ranging from 3 weeks to more than 2 years, following processing that contributes to the development of the flavor and texture of the cheese. The moisture content of these cheeses ranges from 30% to 55% and the pH ranges from 5.0 to 5.3.

Standardization of the Milk   Casein and fat contents of the milk are standardized to minimize variations in the quality of the cheese due to seasonal effects and variation in the milk supply. The casein-to-fat ratio can be adjusted by the addition of skim milk, cream, milk powder, or evaporated milk or the removal of fat. Calcium chloride (0.1%) may also be added to improve coagulation of the milk by rennet and further processing of the cheese. The actual casein and fat content of the milk will vary

for each cheese type and influence the curd formation, cheese yield, fat content, and texture of the cheese (Banks 1998).

Coagulation of the Milk Proteins   Aggregation of the casein micelles to form a three-dimensional gel protein network is initiated through the addition of rennet or other proteolytic enzymes or the addition of acid. Fat and water molecules are also entrapped within this protein network. Enzymes and starter bacteria also tend to associate with the curds, and thus contribute to a number of biochemical changes that occur during the ripening process. The whey, which includes water, salts, lactose, and the soluble whey proteins, is expelled from the gel. The aggregation of the casein micelles by either enzyme or acid treatment results in gels with different characteristics.

In most natural, aged cheeses, coagulation of the casein proteins by the addition of rennet is most common. This process is temperature dependent, with no coagulation occurring below 10°C, and an increase in coagulation rate accompanying an increase in temperature until the optimal temperature for coagulation at 40–45°C. Above 65°C, the enzyme is inactivated (Fox 1969, Brulé et al. 2000). The aggregation of the casein micelles is influenced by temperature ($Q_{10} \sim 12$) to a greater degree than the enzymatic hydrolysis of κ-casein ($Q_{10} \sim 2$) (Cheryan et al. 1975). Aggregation of the micelles begins when approximately 70–85% of the κ-casein molecules are hydrolyzed, which reduces the steric hindrance between the micelles. Reducing the pH or increasing the temperature reduces the degree of casein hydrolysis necessary for coagulation (Fox and McSweeney 1997). The presence of Ca^{2+} ions further facilitates the aggregation of the casein micelles through the neutralization of the negative charge on the micelle and the formation of ionic bonds. The resulting gel has an irregular network, is highly elastic and porous, and exhibits a high degree of syneresis.

The production of acid by lactic acid bacteria or the direct addition of hydrochloric or lactic acid can also result in the aggregation of the casein micelles and formation of clots. As the pH of the milk is reduced, the casein micelles become insoluble and begin to aggregate. Because calcium phosphate is solubilized as the pH of the milk drops, the gel formed during acid coagulation is not stabilized by Ca^{2+} ions. The acid-coagulated gels are less cohesive and exhibit less syneresis than enzyme-coagulated cheeses. These cheeses generally have a high moisture content and low mineral content. Acid coagulation is most frequently used in the manufacture of cottage cheese and other unripened cheeses.

A few unique types of cheese are prepared through acid coagulation of whey or a blend of whey and skim milk in conjunction with heat treatment. Ricotta cheese is the most common cheese prepared in this manner.

Lactic acid bacteria cultures are added to the milk in conjunction with the rennet in ripened cheeses. Although the lactic acid bacteria cultures do not have a significant role in the coagulation of casein, they contribute to the changes that occur during the ripening process. The different strains of starter cultures differ in characteristics including growth rate, metabolic rate, phage interactions, proteolytic activity, and flavor promotion (Stanley 1998). Frequently, mixed-strain cultures, which

Table 23.2. Comparison of Processing Characteristics of Different Types of Ripened, Natural Cheeses

| Cheese | Starter Cultures | Ripening | Scald Temperature | Other Treatments | Composition (%) | | |
					Moisture	Fat	Salt
Very hard							
Romano	Thermophilic cultures	18–24 mo at 16–18°C	45–48°C		23.0	24.0	5.5
Hard: Ripened by bacteria, without eyes							
Cheddar	Mesophilic D cultures	0.5–2 yr at 6–8°C	37–39°C	Curds are cheddared prior to salting, dry salting	37.0	32.0	1.5
Hard: Ripened by bacteria, with eyes							
Emmental	Thermophilic cultures and propionibacteria	10–14 d at 10–15°C; 3 wk–2 mo at 20–24°C; 1–2 mo at 7°C	55°C	Brine-salted	35.5	30.5	1.2
Swiss	Thermophilic cultures, *Pr. freudenreichii* ssp. *shermanii*	7–14 d at 21–25°C; 6–9 mo at 2–5°C	50–53°C	Brine-salted	37.1	27.8	0.5
Semisoft: Ripened principally by bacteria, without eyes							
Colby	Mesophilic D cultures	2–3 mo at 3–4°C	37–39°C	Curds and whey stirred after cooking, as whey is drained	38.2	32.1	1.5
Provalone	L. bulgaricus	1–12 mo at 15–16°C	44–50°C	Curd—knead and stretch in 85–90°C water	42.5	27.0	3.0
Mozzarella	Thermophilic cultures	<1 mo	41°C	Curd—kneaded and stretched in 70°C water	54.0	18.0	0.7
Feta	Thermophilic or mesophilic starter culture	7 d in salt brine at 14–16°C; 2 mo at 3–4°C	Not cooked	From sheep or sheep/goat milk	59.7	20.3	2.2

Semisoft: Ripened principally by bacteria, with eyes							
Gouda	Mesophilic DL culture	2–3 mo at 15°C	36–38°C	Curd washed with hot water, stirred for 30 min at 36–38°C, pressed under whey, brine salted	41.0	28.5	2.0
Edam	Mesophilic DL culture	6 wk–6 mo	36°C	Similar to Gouda, made from semiskimmed (2.5% fat) milk	43.0	24.0	2.0
Semisoft: Ripened by bacteria and surface microorganisms							
Limburger	Mesophilic DL culture	2–3 wk at 10–15°C; 3–8 wk at 4°C (wrapped in foil)	37°C	Whey drained and replaced with salt brine, surface smeared with microflora during initial ripening	45.0	28.0	2.0
Semisoft: Ripened principally by blue mold in the interior							
Roquefort	Indigenous microflora	3–5 mo in limestone caves at 5–10°C and 95% relative humidity	Not cooked	Ewe's milk. Curds mixed with *Penicillium roqueforti* spores. Cheeses are pierced during ripening	40.0	31.0	3.5
Soft: Ripened principally by surface molds							
Camembert	Mesophilic DL culture	10–12 d at 12°C, 7–10 d at 7°C	Not cooked	Surface mold growth by *Penicillium camemberti*	52.5	23.0	2.5

contain unknown numbers of strains of the same species, are used. Mesophilic L cultures contain *Leuconostoc* species, including *Ln. mesenteroides* ssp. *cremoris* and *Ln. lactis,* while the main species in mesophilic D cultures *Lactococcus lactis* ssp. *cremoris* with lesser amounts of *Lc. lactis* ssp. *lactis.* Mesophilic DL cultures would consist of both lactococci and leuconostoc. The thermophilic cultures consist of *S. thermophilus*, and either *Lactobacillus helveticus, Lb. delbrueckii* ssp. *lactis* or *Lb. delbrueckii* ssp. *bulgaricus.*

Cutting the Coagulum   Cutting the coagulum increases the drainage of the whey from the curds and contributes to a sharp decrease in the moisture content of the curds. Acid-coagulated and rennet-coagulated cheeses differ in the pH at which curd formation occurs, and subsequently the pH at which the coagulum is cut. For acid-coagulated cheeses, curd formation occurs at

pH 4.6, the isoelectric point of casein. Curd formation of rennet-coagulated cheeses occurs at higher pHs, ranging from pH 6.3 to 6.6. Following the cutting of the coagulum, the curd and whey mixture is heated and agitated in a process called "scalding." The agitation is necessary to keep the curds suspended in the whey and to promote drainage of whey from the curds. The temperature during the scalding process is dependent on the type of the cheese and ranges from 20°C to 55°C. The temperature affects gel formation, gel viscoelasticity, and regulates the growth of the lactic acid bacteria. A high temperature results in greater drainage from the cheese and a firmer cheese.

The conversion of lactose to lactic acid by starter cultures decreases the pH of the curd, which contributes to the loss of the whey from the curd and a decrease in moisture content. While the curds are in the whey, diffusion of lactic acid into the whey and lactose into the curds occurs. The rate of acid production is affected by the amount and type of the starter cultures, composition of the milk, and temperature during acid production.

When the required acidity of the cheese curds is reached, the whey is drained to recover the curds. Following the separation of the curds from the whey, acid production continues at an increased rate, because of the lack of diffusion of the lactic acid from the curd. To minimize excess acid development following the drainage of the whey, some types of cheese include a washing step to reduce the lactose content. The moisture content of the curd is affected by the extent the coagulum is cut, the temperature of the curd after cutting, and agitation of the curd in the whey.

The handling of the curd following the cutting of the coagulum greatly affects the characteristics of the cheese. The cheddaring process, used in the manufacture of Cheddar, Colby, Monterey, and Mozzarella cheeses, involves piling blocks of curd on top of each other with regular turning to allow the curds to fuse together. In Colby and Monterey cheeses, vigorous stirring during the drainage of the whey inhibits the development of a curd structure and results in the softer cheese with a higher moisture content. Frequently, the whey may be partially drained off and replaced with water or salt brine to remove lactose and reduce the development of acidity, as is done in the processing of Gouda and Limburger cheeses.

Shaping and Pressing   The resulting curds are shaped to form a coherent mass that is easy to handle. The curds are placed in a mold and are often pressed with an external force to cause the curds to deform and fuse. The pressure and time of pressing range from a few g/cm^2 for a few minutes for moist cheeses, to 200 to 500 g/cm^2 for up to 16–48 hours for cooked and hard cheeses. The temperature (20–27°C) and humidity (95% relative humidity) of the pressing room is controlled to optimize the growth of the lactic acid bacteria and facilitate the deformation and shaping of the curd. Acid production by lactic acid bacteria and additional drainage of whey from the curd continues during the shaping and pressing stage. The deformability is affected by the composition of the cheese, and increases until the curds reach a pH of 5.2–5.3. Deformability also increases with an increase in moisture content and temperature.

Salting The salting step reduces the moisture content of the curd, inhibits the growth of starter bacteria, and affects the flavor, preservation, texture, and rate of ripening of the cheese. Final salt contents of cheeses range from 0.7% to 4% (2–10% salt in moisture contents). The amount of salt, the method for application of the salt, and the timing of the salting is dependent on the specific type of cheese. The salt may be incorporated through (1) mixing with dry milled curd pieces, (2) rubbing onto the surface of the molded cheese, or (3) immersing the cheese in a salt brine. Following the salting step, the salt diffuses into the interior of the cheese, with the subsequent displacement of whey. Depending on the size of the cheese block and the composition of the cheeses, it may take from 7 days to over 4 months for the salt to equilibrate within the cheese.

Ripening Fresh, green cheese has a bland flavor and a smooth, rubbery texture. During the ripening process, the characteristic texture and flavor of the cheese develop through a complex series of biochemical reactions. Ripening starter cultures are selected to develop the texture and flavor characteristics of the specific cheese type. Enzymes released following lysis of the microorganisms catalyze the degradation of proteins, lipids, and lactose in the cheese to produce volatile flavor compounds, which contribute to the characteristic flavor of the cheeses. As the ripening time increases, the moisture content of the cheese decreases and the intensity of the flavor increases. The resulting quality attributes of the finished cheese depend on the initial composition of the milk and the starter cultures used, the water activity of the cheeses, and the temperature, time, and humidity during the ripening period. Depending on the type of cheese, the ripening period can range from 3 weeks to more than 2 years.

The ripening temperature influences the rate of the microbial growth and enzyme activity during the process and the equilibrium between the biochemical reactions that occur during ripening. Ripening temperatures generally range from 5°C to 20°C, which is well below the optimum temperatures for microbial growth and enzyme activity. Soft cheeses are often ripened at 4°C to slow the biochemical processes. An increase in ripening temperature for hard cheeses reduces the ripening time necessary for flavor development, with a 5°C increase in ripening temperature reducing the ripening time 2–3 months. However, caution must be exercised in altering ripening temperatures since not all microorganisms and enzymes respond to temperature changes in the same manner, resulting in an imbalance in flavor characteristics (Choisy et al. 2000).

The growth of most of the starter bacteria added to the milk in the initial stages of cheese-making is slowed as the pH of the cheese approaches 5.7 and following the addition of salt, however fermentation and a decrease in pH continue. The fermentation of lactose to lactic acid by the starter cultures provides an environment that prevents the growth of undesirable microorganisms through the reduced pH and the formation of an anaerobic environment. The reduced pH also has an influence on activity of the proteases and lipases, which contribute to the formation of critical volatile flavor compounds. The optimal activity for proteases is between pH 5.5 and 6.5 and for lipases is between pH 6.5 and 7.5. Lactose and citrate are precursors for

a number of volatile flavor compounds, including diacetyl, acetoin, 2,3-butanediol, and acetaldehyde, which are also formed during ripening (Urbach 1995).

Protease and lipase activity during the ripening is probably most important to the development of the flavor and texture of the cheese. Enzymes of the starter bacteria, nonstarter lactic acid bacteria, and secondary cultures added during cheese-making are most important in the development of the flavor and texture of the cheese during ripening. These enzymes are released by the lysis of the cell wall of the bacteria. Rennet enzymes and endogenous milk enzymes, such as plasmin, also contribute to these hydrolytic reactions during ripening. The extent of these enzymatic reactions depends on the activity and specificity of the enzymes, the concentration of the substrates, pH, water activity, salt concentration, and ripening temperature and duration. The degradation of the amino acids and fatty acids, through enzymatic and nonenzymatic reactions, results in the formation of several important volatile flavor compounds, including sulfur-containing compounds, amines, aldehydes, alcohols, esters, and lactones.

Rennet and plasmin are associated with the primary phase of proteolysis and hydrolyze the caseins to large polypeptides. This proteolysis alters three-dimensional protein network of the cheese to form a less firm and less elastic cheese. Although these polypeptides do not have a direct impact on flavor, they do function as a substrate for the proteases associated with the starter and nonstarter bacteria. However, if the primary proteolysis is extensive, bitter peptides, with a high percentage of hydrophobic amino acids predominate. Free amino acids and short-chain peptides contribute sweet, bitter, and brothy-like taste characteristics to the cheese. Further degradation and chemical reactions of these peptides and amino acids through the action of decarboxylases, transaminases, or deaminases, contribute to the formation of amines, acids, ammonia, and thiols, which contribute to cheese flavor.

Lipases break down triacylglycerols into free fatty acids, and mono- and diacylglycerols. The short-chain free fatty acids contribute to the sharp, pungent flavor characteristics of the cheese. The degree of lipolysis that is acceptable without producing soapy and rancid flavors depends on the type of cheese. Several *Penicillium* strains form methyl ketones, lactones, and unsaturated alcohols through their enzymatic systems associated with β-oxidation and decarboxylation, β-oxidation and lactonization, and lipoxygenase activity. Aliphatic and aromatic esters are synthesized by esters present in a range of microorganisms, including mesophilic and thermophilic lactic acid bacteria (Choisy et al. 2000).

The texture of cheese is attributed to the three-dimensional protein network, which entraps fat and whey. This structure is altered through proteolysis during ripening to form a less firm and less elastic cheese.

Carbon dioxide produced by the metabolism of the bacteria and entrapped within the curd results in the formation of eyes in several types of cheeses. The small eyes characteristics of Edam, Gouda, and related cheese varieties are formed by carbon dioxide produced from citrate by *Leuconostoc* ssp. In Swiss-type cheeses, *Propionibacterium freudenreichii*

ssp. *shermanii* metabolize lactate to form the carbon dioxide responsible for the eye formation. These cheeses are ripened in hot rooms (20–22°C) to optimize the growth of the propionibacteria and allow eye formation.

Ripening of cheese is a time-intensive process; thus, there is much interest in accelerating the ripening process without an adverse effect on cheese quality. Addition of enzymes, including the use of encapsulated enzymes; addition of attenuated or modified starter cultures and adjunct cultures; elevated ripening temperatures; and the addition of cheese slurry have been explored as possible means to shorten the ripening processing. An important consideration is that increased proteolysis or an imbalance of enzyme activity can result in higher contents of hydrophobic amino acids and peptides that contribute to bitterness (Choisey 2000, Law 2001, Azarnia et al. 2006).

Processed Cheese

Processed cheeses are produced by blending and heating several natural cheeses with emulsifiers, water, butterfat, whey powder and/or caseinates to form a homogeneous mixture. The proportion of cheese used in the formulation ranges from 51% for cheese spreads and cheese foods to 98% in processed cheeses. Different types of natural cheeses will produce processed cheeses with different flavor and textural characteristics. The formulation of these ingredients affects the consistency, texture, flavor, and melting characteristics of the processed cheese. The heating process inactivates the microorganisms and denatures enzymes to produce a stable product. The flavor of the processed cheese is generally milder than the natural cheeses, due to the effects of the heat. However, the melting properties of the processed cheese are much improved due to the addition of the emulsifiers. Processed cheeses range in consistency from block cheese to sliced cheese to cheese for spreading. (Banks 1998, Fox et al. 2000).

BUTTER

Flavor and consistency are the most important quality attributes to consider during the processing of butter. The characteristic flavor of butter is a result of the formation of diacetyl by heterofermentative lactic acid bacteria. Off-flavors due to lipolysis, oxidation, or other contaminants should be avoided. The butter should be firm enough to hold its shape, yet soft enough to spread easily. Modification of the cow's diet to increase contents of polyunsaturated fatty acids and conjugated linoleic acids in the milk (Avramis et al. 2003, Bobe et al. 2007) or selecting cows that produce milk with a higher content of unsaturated fatty acids (Bobe et al. 2003) results in butter with a softer texture and the potential for improved cold spreadability due to decrease in the content of saturated fatty acids. Figure 23.2 outlines the process involved for making butter and the by-product buttermilk.

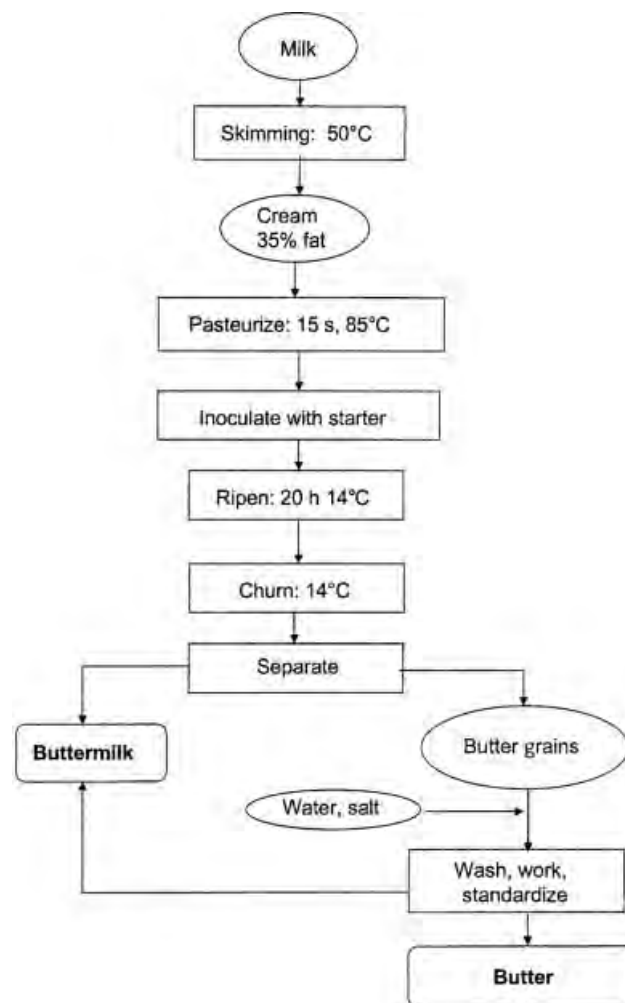
The first step in the processing of butter is skimming the milk to obtain cream with a fat content of at least 35%, in which the fat is dispersed as droplets within the aqueous phase. This step increases the efficiency of the process through increasing the yield of butter, reducing the yield of buttermilk, and reducing


Figure 23.2. Processing scheme for butter processed from ripened cream.

the size of machinery needed. The pasteurization step functions to kill microorganisms, to inactivate enzymes, and to make the butter less susceptible to oxidative degradation. Following pasteurization, the cream is inoculated with a starter culture mixture (1–2%) of *Lactococcus* ssp. and *Leuconostoc* ssp., which contributes to the development of the characteristics butter flavor. It is desirable that the starter cultures grow rapidly at low temperatures. During ripening, the cream begins to ferment and the fat begins to crystallize. The formation of lactic acid and diacetyl by the starter cultures contributes to flavor development in the butter and buttermilk. Crystallization of the fat is important to maximize the yield of the butter and minimize loss of fat into the buttermilk during the churning process. During the churning process, air is incorporated into the cream using dashboards or rotary agitators contributing to the aggregation of fat globules to form butter granules. The resulting butter grains may be washed with water to remove nonfat solids followed by working or kneading the butter grains. During the working step, a

water-in-oil emulsion is formed as the small water droplets are dispersed into the fat matrix.

The churning process is probably most critical to the textural quality of the butter. As air is incorporated into the cream, the fat globules surround the air bubbles and coalesce with other fat-coated air bubbles to form clumps. These clumps continue to coalesce during the churning process and the volume of air bubbles decreases. The proportion of solid fat, which is influenced by temperature, is critical to the aggregation of fat clumps to form butter. If the rate of churning is too fast, the fat globules are less stable and less likely to coalesce, resulting in a greater loss of fat into the buttermilk.

BUTTERMILK

Natural buttermilk is a by-product of butter manufacture (Figure 23.2) and is categorized as sweet (nonfermented) or acidic (fermented). Sweet and acid buttermilk are obtained from the manufacture of butter from nonfermented, sweet cream and sour or cultured cream, respectively. In general, the composition of buttermilk is similar to that of skim milk, consisting of milk proteins, lactose, minerals, and some lipids. The fat content of natural buttermilk is approximately 0.4% and consists primarily of the membrane components of the fat globules. Churning disrupts the fat globules and the MFGM associates with the buttermilk fraction. The MFGM is characterized as having a higher content of phospholipids and unsaturated fatty acids than found in whole milk. The high phospholipid content provides emulsification ability and expands the functionality of buttermilk as a dairy ingredient. However, because of the high content of unsaturated fatty acids associated with the membrane lipids, natural buttermilk has a characteristic flavor and is also more susceptible to the development of oxidized off-flavors (Sodini et al. 2006).

Cultured buttermilk and cultured skim milk are more frequently produced as alternatives to the traditional buttermilk (Figure 23.3). The solids-not-fat and fat contents of cultured buttermilk range from 7.4% to 11.4% and 0.25% to 1.9%, respectively. The homogenized and pasteurized milk with the desired fat content is inoculated with a 1% starter culture of *Lc. lactis* ssp. *lactis* and *Lc. lactis* biovar. *diacetylactis* and *Ln. mesenteroides* ssp. *cremoris*. These bacteria metabolize citrate to diacetyl to contribute to the development of "buttery" flavor. Acid is produced by these bacteria at a relatively slow rate.

Only a minor percentage of the buttermilk produced is consumed directly. The commercial use of buttermilk includes applications in the baking and dairy industries (Sodini et al. 2006). For many of these applications, the buttermilk is concentrated by evaporation and spray dried to form a powder. Spray drying has been shown to result in a significant decrease in the phospholipid content, which could have important implications with respect to the functionality of buttermilk powders as an ingredient (Morin et al. 2007).

SOUR CREAM

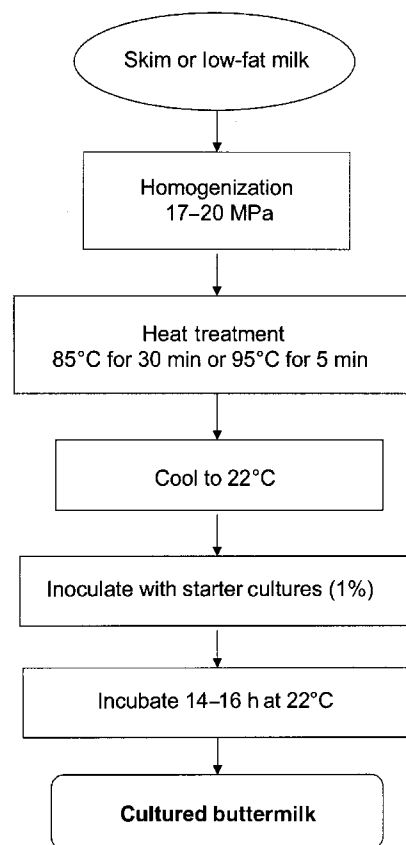
Sour cream is produced from pasteurized, homogenized cream (20–30% fat) and has a pleasant acidic taste and buttery aroma


Figure 23.3. Processing scheme for cultured buttermilk.

(Fig. 23.4). Low-fat sour cream has a fat content ranging from 10% to 12%. Following standardization of the milk and cream to the desired fat content, the mixture is warmed and homogenized to improve the consistency of the final product. The starter cultures include *Lc. lactis* ssp. *lactis* and *Lc. lactis* biovar. *diacetylactis* and *Ln. mesenteroides* ssp. *cremoris*. As in buttermilk, these cultures contribute to the acid and buttery flavor of the sour cream. The sour cream may be packaged prior to or following fermentation at 20°C until the pH is reduced to 4.5. Packaging prior to fermentation results in a thicker product because the gel is not disturbed. As the pH decreases, the fat clusters aggregate to form a viscous cream. Rennet or thickening agents, such as starch, guar gum, carrageenan, and locust bean gum, are sometimes added to increase the firmness of the sour cream and stabilize the gel to minimize syneresis (Hunt and Maynes 1997).

YOGURT

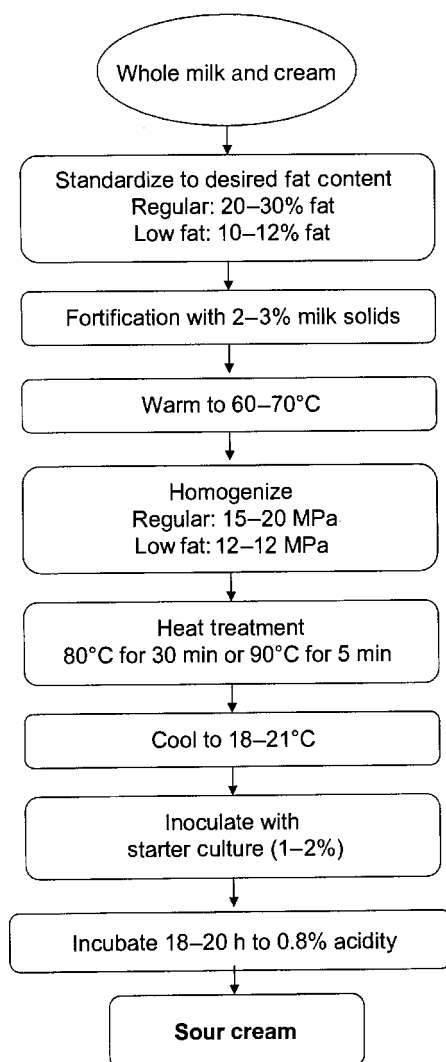
The tremendous increase in the popularity of yogurt in recent decades has been attributed to its health food image and the wide diversity of flavors, compositions, and viscosities available to consumers. The manufacturing methods, raw materials, and


Figure 23.4. Processing scheme for sour cream.

Figure 23.5. Processing scheme for set-style and stirred-style yogurt.

formulation vary widely from country to country resulting in products with a diversity of flavor and texture characteristics. While in many Western societies, yogurt is produced from cows' milk, other mammalian milk can be used to produce yogurt. Figure 23.5 outlines the steps involved in the processing of stirred-style and set-style yogurt.

The milk is initially standardized to the desired fat (0.5–3.5% fat) and milk solids-not-fat (12.5%) contents. The increase in the protein content is most commonly achieved through the addition of nonfat milk powder and improves the body and decreases syneresis of the final product. In addition to decreasing the size of the fat globule, homogenization of the milk alters the milk proteins to reduce syneresis and increase firmness (Tamime and Robinson 1999b). The subsequent heat treatment (85°C for 30 minutes) eliminates pathogenic microorganisms and reduces the oxygen in the milk to provide a good growth media for the

starter cultures. Enzymes and the major whey proteins, including β-lactoglobulin and α-lactalbumin, but not the casein proteins are also denatured by the heat treatment. The denaturation of the whey proteins and subsequent interactions between the whey proteins and casein and/or fat globules improves the stability of the gel and increases water-binding capacity of the caseins to decrease syneresis (Tamime and Robinson 1999b).

Following heat treatment, the milk is cooled to 43–45°C for inoculation of the starter cultures. The fast acid-producing thermophilic lactic acid bacteria, *Streptococcus salivarius* ssp. *thermophilus* and *Lactobacillus delbrueckii* ssp. *bulgaricus* are the primary microorganisms used in the production of yogurt. These bacteria have a synergistic effect on each others' growth and should be present in approximately equal numbers for optimal flavor development. *Lb. delbrueckii* ssp. *bulgaricus* has important protease activity and hydrolyzes the milk proteins to small peptides and amino acids. These peptides and amino acids enhance the growth of *S. thermophilus,* which has limited proteolytic activity. *S. thermophilus* metabolizes pyruvic acid to formic acid and carbon dioxide, which in turn, stimulates the

growth of *Lb. delbrueckii*. Initially, *S. thermophilus* grows faster than *Lb. delbrueckii*, however, at the later stages of the fermentation process, the growth of the *S. thermophilus* is inhibited by the reduced pH of the yogurt. The mutual stimulation of the yogurt cultures through their metabolic activity significantly increases the formation of lactic acid at a rate greater than would be possible by the individual cultures.

The acid produced by the yogurt cultures decreases the pH of the milk to cause the aggregation of the casein micelles. As the pH decreases to less than 6.0, the colloidal calcium phosphate that stabilizes the casein micelle structure is solubilized and micelle undergoes partial rearrangement. Solubilization of the colloidal calcium phosphate is essentially completed when the milk reaches a pH of 5.0. With further acid production, the pH of the milk reaches the isoelectric point of casein (pH 4.6) and electrostatic repulsion of the charged groups on the casein proteins decreases as these groups become protonated. The increased casein–casein association through hydrophobic interactions results in the aggregation of casein micelles and gel formation (Lucey 2002). Complete solubilization of colloidal calcium phosphate prior to the initiation of gel formation results in the formation of yogurt with stronger gels and reduced tendency for syneresis. Higher inoculation rates for the starter cultures (2%) and a lower incubation temperature (40°C) contribute to stronger interactions between casein molecules and a more stable gel structure and reduced syneresis (Lee and Lucey 2004).

Two types of yogurt, set-style and stirred-style are produced. Set-style yogurt is fermented following packaging, with color and flavors added to the container prior to the addition of the inoculated milk, resulting in a gel that forms a firm, unbroken coagulum. Stirred-style yogurt is fermented in a vat prior to packaging, with the gel structure broken following fermentation during the addition of flavors and colors, cooling and packaging stage. For both types of yogurt, either a short incubation period at 40–45°C for $2\frac{1}{2}$–3 hours or a long incubation period at 30°C for 16–18 hours may be used to attain a pH of 4.5 or titratable acidity of 0.9% lactic acid prior to cooling.

The metabolism of the yogurt cultures contributes to the characteristic flavor of yogurt. Both bacteria are heterofermentative and produce lactic acid from glucose, yet are unable to metabolize galactose. Acetaldehyde, a key flavor component of yogurt described as having a fruity aroma, is produced by the degradation of threonine to acetaldehyde and glycine by the enzyme threonine aldolase. Although *S. thermophilus* forms a majority of the acetaldehyde produced, the proteolytic activity of *Lb. delbrueckii* ssp. *bulgaricus* generates the precursors for the formation of acetaldehyde (Wilkins et al. 1986). Other volatile flavor compounds generated by the metabolism of lactic acid bacteria include diacetyl and 2,3-pentanedione, both of which have buttery aroma characteristics. The formation of lactic acid during the fermentation is also a critical contributor to the typical yogurt flavor (Ott et al. 1997, 2000).

Syneresis, the expelling of interstitial liquid due to association of the protein molecules and shrinkage of a gel network, is undesirable in yogurt. Syneresis increases with an increase in incubation temperature. In stirred yogurt, extensive amounts of syneresis results in a thin product. Therefore, incubation of the yogurt at a lower temperature, such as 32°C, is recommended to maintain the desirable viscosity. Stabilizers, such as gelatin, xanthan gum, locust bean gum, and κ-carrageenan, increase the firmness and viscosity of yogurt and minimize syneresis through their ability to bind with water and the milk proteins to stabilize the protein network (Soukoulis et al. 2007).

ACIDOPHILUS MILK

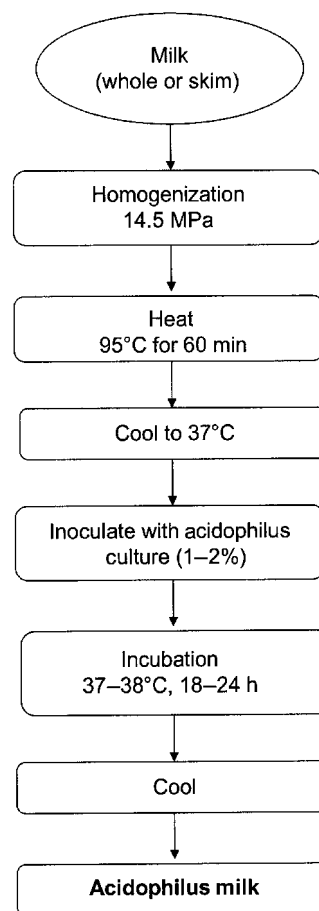
Acidophilus milk was developed as a fluid milk product that provides therapeutic benefits through the alleviation of intestinal disorders. Following homogenization and heat treatment of the milk to minimize contamination by other microorganisms, the milk is cooled to 37°C and inoculated with a 1% culture of *Lactobacillus acidophilus* (Fig. 23.6). The milk is incubated at this temperature for 18–24 hours until the titratable acidity reaches 0.63–0.72%. *Lb. acidophilus* is a thermophilic starter that grows slowly in milk and has a relatively high acid-tolerance. To provide the desired therapeutic effects, the milk


Figure 23.6. Processing scheme for acidophilus milk.

should contain 5×10^8 cfu/mL at the time of consumption (Tamime and Marshall 1997).

THE FUTURE—CULTURED DAIRY PRODUCTS WITH THERAPEUTIC BENEFITS

The availability of dairy products with positive nutritional benefits, in addition to yogurt and acidophilus milk, is expected to increase in the future. Probiotic bacteria, galactooligosaccharides and other lactose derivatives, prebiotics, bioactive peptides, whey proteins, and conjugated linoleic acids are among the components identified in cultured dairy products with enhanced nutritional benefits, ranging from improved balance of intestinal function, reduction of serum cholesterol, enhanced immune function, and anticarcinogenic and antimicrobial activity. In some cases, modifications of the traditional processing protocols will be necessary to increase the content and stability of these components in cultured dairy products without adversely affecting the flavor, texture, and other sensory quality attributes. The development of cultured dairy products with improved health benefits will provide numerous challenges and rewards to food scientists and consumers (McIntosh et al. 1998, Hilliam 2003, Korhonen and Pihlanto 2003, Parodi 2003, Playne et al. 2003, Stanton et al. 2003, Stevenson and Knowles 2003).

Chemistry and Biochemistry of Milk Constituents

P.F. Fox and A.L. Kelly

Abstract: Mammalian milk is a highly complex physicochemical system, containing colloidal proteins (the casein micelle) and emulsified lipids, as well as dissolved lactose, minerals, vitamins and minerals. The properties of milk, and the products made or isolated from milk, are very much determined by the properties of its constituents. These properties are particularly relevant when milk is processed, for example through denaturation of proteins, oxidation, hydrolysis of proteins and lipids, or Maillard reactions involving lactose. In this chapter, the principal families of milk constituents, and their most significant characteristics, are described.

INTRODUCTION

Milk is a fluid secreted by female mammals, of which there are approximately 4500 species, to meet the complete nutritional, and some of the physiological, requirements of the neonate of the species. Because nutritional requirements are species-specific and change as the neonate matures, it is not surprising that the composition of milk shows very large interspecies differences, for example the concentrations of fat, protein and lactose range from 1% to 50%, 1% to 20% and 0% to 10%, respectively. Interspecies differences in the concentrations of many of

the minor constituents of milk are even greater than those of the macro constituents. The composition of milk also changes markedly during lactation, reflecting the changing nutritional requirements of the neonate and during mastitis and physiological stress. In this chapter, the typical characteristics of the principal, and some of the minor, constituents of bovine milk will be described. The milk of the principal dairying species, cow, buffalo, sheep and goat are generally similar but differ in detail. The milks of several non-bovine species are described by Park and Haenlein (2006) and Fuquay et al. (2011); the latter includes articles on monotremes and marsupials, marine mammals and primates.

Sheep and goats were domesticated around 8000 BC and their milk has been used by humans since. However, cattle, especially breeds of *Bos taurus*, are now the dominant dairy animals. Total recorded world milk production is approximately 600 × 10^6 tonnes/annum, of which approximately 85% is bovine, 11% is buffalo and 2% each is from sheep and goats. Camels, mares, reindeer and yaks are important dairy animals in limited geographical regions with specific cultural and/or climatic conditions.

Milk is a very flexible raw material; several thousand dairy products are produced around the world in a great diversity of flavours and forms, including about 1400 varieties/variants of cheese. The principal dairy products and the percentage of milk used in their production are: liquid (beverage) milk, approximately 40%; cheese, approximately 35%; butter, approximately 32%; whole milk powder, approximately 6%; skimmed milk powder, approximately 9%; concentrated milk products approximately 2%; fermented milk products, approximately 2%; casein, approximately 2% and infant formulae, approximately 0.3%. The flexibility of milk as a raw material is a result of the properties, many of them unique, of its principal constituents; many of these are very easily isolated, permitting the production of valuable food ingredients. Milk is free of off-flavours, pigments and toxins, which greatly facilitates its use as a food or as a raw material for food production.

The processability and functionality of milk and milk products are determined by the chemical and physicochemical properties of its principal constituents, that is lactose, lipids, proteins, and salts, which will be described in this chapter. The exploitation and significance of the chemical and physico-chemical properties of milk constituents in the production and properties of the principal groups of dairy foods, that is liquid milk products, cheese, butter, fermented milks, functional milk proteins and lactose will be described in Chapter 25. Many of the principal problems encountered during the processing of milk are caused by variability in the concentrations and properties of the principal constituents arising from several factors, including breed, individuality of the animal (i.e., genetic factors), stage of lactation, health of the animal, especially mastitis, and nutritional status. Synchronised calving, as practised in New Zealand, Australia and Ireland, to avail of cheap grass as the principal component of the cow's diet, has a very marked effect on the composition and properties of milk (see O'Brien et al. 1999a, b, c, Mehra et al. 1999). However, much of the variability can be offset by standardising the composition of milk using various methods (e.g., centrifugation, ultrafiltration or supplementation) or by modifying the process technology.

The chemical and physico-chemical properties of the principal constituents of milk are well characterised and described. The very extensive literature includes the following textbooks: Walstra and Jenness (1984), Wong et al. (1988), Fox (1992, 1995, 1997, 2003a), Fox and McSweeney (1998, 2003, 2006), Walstra et al. (1999, 2005) and McSweeney and Fox (2009).

SACCHARIDES

LACTOSE

Introduction

Lactose is a reducing disaccharide comprising glucose and galactose, linked by a $\beta1$–4-O-glycosidic bond (Fig. 24.1). It is unique to milk and is synthesised in the mammary gland from glucose transported from the blood; one molecule of glucose is epimerised to galactose, as UDP-galactose (Gal), *via* the Leloir pathway and is condensed with a second molecule of glucose by a two-component enzyme, lactose synthetase. Component A is a general UDP-galactosyl transferase (UDP-GT; EC 2.4.1.2.2), which transfers galactose from UDP-Gal to a range of sugars, peptides or lipids. Component B is the whey protein, α-lactalbumin (α-La), in the presence of which, the K_M of UDP-GT for glucose is reduced 1000-fold and lactose is the principal product synthesised. There is a good correlation between the concentrations of lactose and α-La in milk. Lactose is responsible for approximately 50% of the osmotic pressure of milk, which is equal to that of blood and varies little; therefore, the concentration of lactose in milk is tightly controlled and is independent of breed, individuality and nutritional factors, but decreases as lactation advances and especially during mastitis, in both cases due to the influx of NaCl from the blood. The physiological function of α-La is probably to control the synthesis of lactose, and thus maintain the osmotic pressure of milk relatively constant.

The concentration of lactose in milk ranges from approximately 0, for some species of seal, to approximately 10% in the milk of some monkeys. The concentration of lactose in the milk of the principal dairy species is quite similar (cow, 4.8%; buffalo, 4.3%; sheep, 4.6%; goat, 4.9%; camel, 5.1%), exceptions are the horse (6.1%), donkey (6.9%) and reindeer (2.5%); human milk contains about 7.0% lactose. The lactose content of bulk herd milk from randomly calved cows varies little throughout the year but differences can be quite large when calving of cows is synchronised, for example in Ireland, the level of lactose in creamery milk varies from approximately 4.8% in May to approximately 4.2% in October.

Chemical and Physico-Chemical Properties of Lactose

Among sugars, lactose has a number of distinctive characteristics, some of which cause problems in milk products during processing and storage; however, some of its characteristics are exploited to advantage.
Figure 24.1. Structures of lactose.

The functional aldehyde group at the C-1 position of the glucose moiety exists mainly in the hemiacetal form, forming a cyclic structure and, consequently, C-1 is a chiral, asymmetric, carbon. Therefore, like all reducing sugars, lactose can exist as two anomers, α and β, which have markedly different properties. From a functional viewpoint, the most important of these properties are differences in solubility and crystallisation characteristics between the isomers; α-lactose crystallises as a monohydrate, while crystals of β-lactose are anhydrous. Since crystalline α-lactose contains 5% H_2O, the yield of this anomer is higher than that of β-lactose and this must be considered when expressing the concentration of lactose. The solubility of α- and β-lactose in water at 20°C is approximately 7 g/100 mL and 50 g/100 mL, respectively. However, the solubility of α-lactose is much more temperature-dependent than that of β-lactose and the solubility curves intersect at approximately 93.5°C (see Fox and McSweeney 1998).

At equilibrium in aqueous solution, lactose exists as a mixture of α and β anomers in the approximate ratio of 37:63. When an excess of α-lactose is added to water, approximately 7 g/100 mL dissolve immediately, some of which mutarotates to give an α:β ratio of 37:63, leaving the solution unsaturated with respect to both α- and β-lactose. Further α-lactose then dissolves, some of which mutarotates to β-lactose. Solubilisation and mutarotation continue until two conditions exist, that is approximately 7 g of dissolved α-lactose/100 mL of water and an α :β ratio of 37:63, giving a final solubility of approximately 18.2 g/100 mL. When β-lactose is added to water, approximately 50 g/100 mL dissolve initially but approximately 18.5 g of this mutarotates to α-lactose, which then exceeds its solubility and some lactose crystallises. This upsets the α:β ratio and more β-lactose mutarotates to α-lactose, which crystallises. Mutarotation of β-lactose and crystallisation of α-lactose continue until approximately 7 g and 11.2 g of α- and β-lactose, respectively, are in solution.

Although lactose has low solubility in comparison with other sugars, once dissolved, it crystallises with difficulty and forms supersaturated solutions. Highly supersaturated solutions (greater than twofold saturated) crystallise spontaneously but if the solution is only slightly supersaturated (one to twofold), lactose crystallises slowly and forms large, sharp, tomahawk-shaped crystals of α-lactose. If the dimensions of the crystals exceed approximately 15 μm, they are detectable on the tongue and palate as a sandy texture. Crystals of β-lactose are smaller and monoclinical in shape. In the metastable zone, crystallisation of lactose is induced by seeding with finely powdered lactose (Fig. 24.2). Since the solubility of α-lactose is lower than that of the β anomer below 93.5°C, α-lactose is the normal commercial form.

When concentrated milk is spray-dried, the lactose does not have sufficient time to crystallise during drying and an amorphous glass is formed. If the moisture content of the powder is kept low (<4%), the lactose glass is stable, but if the moisture content increases to about 6%, for example on exposure of the powder to a high-humidity atmosphere, the lactose will crystallise as α-lactose monohydrate. If extensive crystallisation occurs, an inter-locking mass of crystals is formed, resulting in 'caking' of the powder, which is a particularly serious problem in whey powders owing to the high content of lactose $\sim$70%). The problem is avoided by pre-crystallising, as much as possible, of the lactose before drying, which is achieved by seeding the concentrated solution with finely powdered lactose.

Controlled agglomeration (caking) is used to improve the wettability of spray-dried milk powder This product has poor wettability because the small particles swell on contact with water, thereby blocking the channels between the particles (see Kelly et al. 2003 for review). The wettability (often incorrectly referred to as 'solubility') of spray-dried milk powder may be improved by controlling the drying process to produce milk
Figure 24.2. Initial solubility of α- and β-lactose, final solubility at equilibrium (line 1) and supersaturation by a factor of 1.6 and 2.1 (α-lactose excluding water of crystallisation) (Fox and McSweeney 1998).

powder with coarser, more easily wetted particles; such powders are said to be 'instantised' and are produced by agglomerating the fine powder particles, in effect by controlling the caking process. In the case of whole milk powder, instantisation processes must also overcome the intrinsic hydrophobic nature of milk fat; this is normally achieved by adding the amphiphilic agent, lecithin. Although lactose is hygroscopic when it crystallises, properly crystallised lactose has very low hygroscopicity and, consequently, is a very effective component of icing sugar.

The crystallisation of lactose in frozen milk products results in destabilisation of the casein, which aggregates when the product is thawed. In this case, the effect of lactose is indirect; when milk is frozen, pure water freezes and the concentration of solutes in the unfrozen water is increased. Since milk is supersaturated with calcium phosphate ($\sim$66% and $\sim$57% of the Ca and PO_4, respectively, are insoluble and occur in the casein micelles, known as colloidal calcium phosphate (CCP); see Section 'Milk Salts'), when the amount of water becomes limiting, soluble $Ca(H_2PO_4)_2$ and $CaHPO_4$ crystallise as $Ca_3(PO_4)_2$, with the concomitant release of H^+ and a decrease in pH to approximately 5.8. During frozen storage, lactose crystallises as α-lactose monohydrate, thus, reducing the amount of solvent water and aggravating the problems of calcium phosphate solubility and pH decline. Thorough crystallisation of lactose before freezing alleviates, but does not eliminate, this problem. Preheating milk prior to freezing also alleviates the problem, but pre-hydrolysis of lactose to the more soluble sugars, glucose and galactose, using β-galactosidase, appears to be the best solution.

Lactose has low sweetness (16% as sweet as sucrose in a 1% solution). This limits its usefulness as a sweetener (the principal function of sugars in foods) but makes it is a very useful diluent, for example for food colours, flavours or enzymes, when a high level of sweetness is undesirable.

Being a reducing sugar, lactose can participate in the Maillard (non-enzymatic) browning reaction, with very undesirable consequences in all dairy products, for example brown colour, off-flavours, reduced solubility and reduced nutritional value. The Maillard reaction, and factors that affect it, has been studied extensively for around 100 years and the relevant literature has been reviewed frequently (see O'Brien 2009, Nursten 2011).

FOOD APPLICATIONS OF LACTOSE

Total milk production ($\sim$600 $\times$ 10^6 tonnes/annum) contains $\sim$30 $\times$ 10^6 tonnes of lactose. Most of this lactose is consumed as a constituent of milk but whey, a by-product of the manufacture of cheese and, to a lesser extent, of casein, contains 8–9 $\times$ 10^6 tonnes of lactose. About 400,000 tonnes of lactose are isolated/prepared per annum. A number of high-lactose food products are also produced, for example approximately 2,000,000 tonnes of whey powder, electrodialysed whey powder and whey permeate powder; these serve as crude sources of lactose for several food products, including infant formulae. Thus, most available lactose is now utilised in some form and little is wasted. The production of lactose is basically similar to that for other sugars, involving concentration, crystallisation, recovery, washing and drying of the crystals (see Paterson 2009, 2011).

Although some of its properties, especially its low sweetness and low solubility, limit the usefulness of lactose as a sugar, other properties, that is very low hygroscopicity if properly crystallised, low sweetness and reducing properties, make it a valuable ingredient for the food and pharmaceutical industries. In the pharmaceutical industry, lactose is widely used as a diluent in pelleting operations. The principal application of lactose in the food industry is in the humanisation of infant formulae; human milk contains approximately 7% lactose, compared to approximately 4.8% in bovine milk. For this application, demineralised whey is widely used; it is cheaper and more suitable than purified lactose because it also supplies whey proteins, which help bring the casein:whey protein ratio of the formulae closer to the value 40:60, found in human milk, compared with 80:20 in bovine milk. It is necessary to demineralise the whey because bovine milk contains approximately 4 times as much inorganic salts as human milk. Demineralisation is accomplished by electrodialysis, ion exchange or nanofiltration or combinations of these.

Lactose is also used as an agglomerating/free-flowing agent in foods (e.g., butter powders), in the confectionery industry to improve the functionality of shortenings, as an anti-caking agent in icing mixtures at high humidity, or as a reducing sugar if Maillard browning is desired. The low sweetness of lactose limits its widespread use as a sugar but is advantageous in many applications. Lactose absorbs compounds and may be used as a diluent for food flavours and colours or to trap flavours.

LACTOSE DERIVATIVES

A number of more useful and more valuable products may be produced from lactose (see Playne and Crittenden 2009). The most significant are the following:

- *Lactulose* (*galactosyl β-1–4 fructose*): A sugar not found in nature, which is produced from lactose by heating, especially under slightly alkaline conditions. The concentration of lactulose in milk is a useful index of the severity of the heat treatment to which milk is subjected, for example in-container sterilisation > indirect ultra-high temperature (UHT) > direct UHT > high-temperature short-time (HTST) pasteurisation. Lactulose is not hydrolysed by intestinal β-galactosidase and enters the large intestine, where it promotes the growth of *Bifidobacterium* spp. It also has a laxative effect and is widely used for this purpose; more than 20,000 tonnes are produced annually.
- *Glucose-galactose syrups, produced by acid or enzymatic (β-galactosidase) hydrolysis* (see Chapter 25): The technology for the production of such hydrolysates has been developed but the product is not cost-competitive with other sugars (sucrose, glucose, glucose–fructose).
- *Tagatose*: Is the keto analogue of galactose. It occurs at a low level in the gum of the evergreen tree, *Sterculia setigera,* and in severely heated milk and stored milk powder. It can be produced by treating β-galactosidase–hydrolysed lactose with a weak alkali, for example $Ca(OH)_2$, which converts the galactose to tagatose, which can be purified by demineralisation and chromatography. Tagatose is nearly as sweet as sucrose, has a good quality taste and enhances the flavour of other sweeteners. It is absorbed poorly from the small intestine, serves as a probiotic and has little effect on blood glucose; it is fermented in the lower intestine to volatile short-chain acids that can be absorbed but provide only approximately 35% of the energy derived from sugars catabolised *via* the normal route. Tagatose has GRAS status and is produced commercially by SweetGredients, a company formed by Arla Foods and Nordzuker (Denmark).
- *Galacto-oligsaccharides*: β-Galactosidase has transferase as well as hydrolytic activity and under certain conditions, the former predominates, leading to the formation of galacto-oligosaccharides containing up to six monosaccharides linked by glycosidic bonds that are not hydrolysed by the enzymes secreted by the human small intestine. The undigested oligosaccharides enter the large intestine, where they have bifidogenic properties and are considered to have promising food applications. These oligosaccharides are quite distinct from the naturally occurring oligosaccharides referred to in Section 'Oligosaccharides'(see Ganzle 2011).
- *Ethanol*: Is produced commercially by the fermentation of lactose by *Kluyveromyces lactis*. Depending on local legislation, the ethanol may be used in alcoholic drinks, which are profitable. The current interest in renewable energy sources has created vast opportunities for lactose-derived ethanol but its commercial success will depend on local taxation policy.

Other derivatives that have limited but potentially important applications include lactitol, lactobionic acid, lactic acid, acetic acid, propionic acid, lactosyl urea and single-cell proteins. Most of these derivatives can be produced by fermentation of sucrose, which is cheaper than lactose, or by chemical synthesis. However, lactitol and lactobionic acids are derived specifically from lactose and may have economic potential. Lactitol is a synthetic sugar alcohol produced by reduction of lactose; it is not metabolised by higher animals but is relatively sweet, and hence has potential for use as a non-calorific sweetener. It has also been reported that lactitol reduces blood cholesterol level, reduces sucrose absorption and is anti-carcinogenic. Lactobionic acid has a sweet taste, which is unusual for an acid and therefore should have some interesting applications.

NUTRITIONAL ASPECTS OF LACTOSE

Lactose is responsible for two enzyme deficiency syndromes: lactose intolerance and galactosemia. The former is due to a deficiency of intestinal β-galactosidase, which is rare in infants but common in adults, except North-Western Europeans and a few African tribes. Since humans are unable to absorb disaccharides, including lactose, from the small intestine, unhydrolysed lactose enters the large intestine where it is fermented by bacteria, leading to flatulence and cramp, and to the absorption of water from the intestinal mucosa, causing diarrhoea. These conditions cause discomfort and perhaps death. Lactose intolerance has been studied extensively since its discovery in 1959 and the literature has been reviewed regularly (see Ingram and Swallow 2009).

The problems caused by lactose intolerance can be avoided by:

- excluding lactose-containing products from the diet, which is the normal practice in regions of the world where lactose intolerance is widespread;
- removing lactose from milk, for example by ultrafiltration;
- hydrolysis of the lactose by adding β-galactosidase at the factory or in the home. The technology for the production of lactose-hydrolysed milk and dairy products is well developed but is of commercial interest mainly for lactose-intolerant individuals in Europe or North America. Because the consumption of milk is very limited in South-East Asia, the use of β-galactosidase is of little interest, although lactose intolerance is widespread.

Galactosemia is caused by the inability to catabolise galactose, owing to a deficiency of either of two enzymes, galactokinase or galactose-1P uridyltransferase (see Flynn 2003). A deficiency of galactokinase leads to the accumulation of galactose that is catabolised *via* alternative routes, one of which leads to the accumulation of galactitol in various tissues, including the eye, where it causes cataracts over a period of about 20 years. A deficiency of galactose-1P uridyltransferase leads to abnormalities in membranes of the brain and to mental retardation unless galactose is excluded from the diet within a few weeks of birth. Both forms of galactosemia occur at a frequency of 1 per approximately 50,000 births.

Lactose in Fermented Dairy Products

The fermentation of lactose to lactic acid, by lactic acid bacteria (LAB) is a critical step in the manufacture of all fermented dairy products (cheese, fermented milks and lactic butter). The fermentation pathways are well established (see Cogan and Hill 1993, Poolman 2002). Lactose is not a limiting factor in the manufacture of fermented dairy products; only approximately 20% of the lactose is fermented in the production of these products. Individuals suffering from lactose intolerance may be able to consume fermented milks without ill-effects, possibly because LAB produce β-galactosidase and emptying of the stomach is slower than that for fresh milk products, thus, releasing lactose more slowly into the intestine.

In the manufacture of cheese, most (96–98%) of the lactose is removed in the whey. The concentration of lactose in fresh curd depends on its concentration in the milk and on the moisture content of the curd and varies from approximately 1.7%, w/w, in fresh Cheddar curd to approximately 2.4%, w/w, in fresh Camembert. The metabolism of residual lactose in the curd to lactic acid has a major effect on the quality of mature cheese (Fox et al. 1990, 2000). The resultant lactic acid may remain essentially unchanged in the cheese during ripening (e.g., Cheddar cheese) or may be catabolised to other compounds, for example CO_2 and H_2O, by surface mould in Camembert, or to propionic acid, acetic acid, H_2O and CO_2 in Emmental-type cheeses. Excessive lactic acid in cheese curd may lead to a low pH and a number of defects, such as a strong, acid, harsh taste, an increase in brittleness and a decrease in firmness. The pH of full-fat Cheddar is inversely related to the lactose/lactic acid content of the curd. Excess residual lactose may also be fermented by heterofermentative lactobacilli, with the production of CO_2 leading to an open texture.

In the manufacture of some cheese varieties, for example Dutch cheese, the curds are washed to reduce the lactose content and thereby regulate the pH of the pressed curd at approximately 5.3. For Emmental, the curd-whey mixture is diluted with water by approximately 20%, again to reduce the lactose content of the curd, maintain the pH at approximately 5.3, and keep the calcium concentration high, which is important for the textural properties of this cheese. For Cheddar, the level of lactose, and hence lactic acid, in the curd is not controlled. Hence, changes in the concentration of lactose in milk, such as those occurring throughout lactation, can result in marked changes in the quality of such cheeses. To overcome seasonal variations in the lactose content of milk, the level of wash water used for Dutch-type cheeses is related to the concentrations of lactose and casein in the milk. Ideally, the lactose-to-protein ratio in any particular variety should be standardised, for example by washing the curd, to minimise variations in the concentration of lactic acid, pH and the quality of cheese.

Oligosaccharides

Lactose is the principal sugar in milk but the milk of most, if not all, species also contains oligosaccharides, up to hexasaccharides, derived from lactose (the reducing end of the oligosaccharides is lactose and many contain fucose and N-acetylneuraminic acid). About 130 oligosaccharides have been identified in human milk; the milk of elephant, bears and marsupials also contains high levels of oligosaccharides. The oligosaccharides are considered to be important sources of certain monosaccharides, especially fucose and N-acetylglucosamine, for neonatal development, especially of the brain (Urashima et al. 2001, 2009, 2011).

MILK LIPIDS

Definition and Variability

The lipid fraction of milk is defined as those compounds that are soluble in non-polar solvents (ethyl/petroleum ether or chloroform/methanol) and is comprised mainly of triglycerides (98%), with approximately 1% phospholipids and small amounts of diglycerides, monoglycerides, cholesterol, cholesterol esters and traces of fat-soluble vitamins and other lipids. The lipids occur as globules, 0.1–20 µm in diameter, each surrounded by a membrane, the milk fat globule membrane (MFGM), which serves as an emulsifier. The concentration of total and individual lipids varies with breed, individual animal, stage of lactation, mastitic infection, plane of nutrition, interval between milking and point during milking when the sample is taken. Among the principal dairy breeds, Friesian/Holsteins produce milk with the lowest fat content ($\sim$3.5%) and Jersey/Guernsey the highest ($\sim$6%). The fat content varies considerably throughout lactation; when synchronised calving is practised, the fat content of bulk Friesian milk varies from approximately 3% in early lactation to >4.5% in late lactation. Such large variations in lipid content obviously affect the economics of milk production and the composition of milk products, but can be modified readily by natural creaming, centrifugal separation or addition of cream, and hence need not affect product quality. Milk lipids also exhibit variability in fatty acid composition and in the size and stability of the globules. These variations, especially fatty acid profile, are essentially impossible to standardise and hence are responsible for considerable variations in the rheological properties, colour, chemical stability and nutritional properties of fat-containing dairy products.

Fatty Acid Profile

Ruminant milk fat contains a wider range of fatty acids than any other lipid system – up to 400 fatty acids have been reported in bovine milk fat; the principal fatty acids are the homologous series of saturated fatty acids with an even number of C-atoms, $C_{4:0}$–$C_{18:0}$, and $C_{18:1}$. The outstanding features of the fatty acid profile of bovine milk fat are a high concentration of short- and medium -chain acids (ruminant milk fats are the only natural lipids that contain butanoic acid, $C_{4:0}$) and a low concentration of polyunsaturated fatty acids.

In ruminants, the fatty acids for the synthesis of milk lipids are obtained from triglycerides in chylomicrons in the blood or synthesised de novo in the mammary gland from acetate or β-hydroxybutyrate produced in the rumen. The triglycerides in

chylomicrons are derived from the animal's feed or synthesised in the liver. Butanoic acid ($C_{4:0}$) is produced by the reduction of β-hydroxybutyrate, which is synthesised from dietary roughage by bacteria in the rumen and therefore varies substantially with the animal's diet. All $C_{6:0}$–$C_{14:0}$ and 50% of $C_{16:0}$ are synthesised in the mammary gland *via* the malonylCoA pathway from acetylCoA produced from acetate synthesised in the rumen. Essentially 100% of $C_{18:0}$, $C_{18:1}$, $C_{18:2}$ and $C_{18:3}$ and 50% of $C_{16::0}$ are derived from blood lipids (chylomicrons) and represent approximately 50% of total fatty acids in ruminant milk fat. Unsaturated fatty acids in the animal's diet are saturated by bacteria in the rumen unless they are protected, for example by encapsulation.

Mainly due to saturation in the rumen, ruminant milk fats are quite saturated, approximately 65% of the fatty acids in bovine milk fat are saturated, and are considered nutritionally undesirable although not all to an equal extent. However, according to Parodi (2009), the case against saturated fatty acids as causative factors for coronary heart disease is not proven and further research is required.

When milk production is seasonal, for example Australia, New Zealand and Ireland, very significant changes occur in the fatty acid profile of milk fat throughout the production season (see Fox 1995, Fox and McSweeney 1998, 2006). These variations are reflected in the hardness of butter produced from such milk; the spreadability of butter produced in winter is much lower than that of summer butter. Owing to the lower degree of unsaturation, winter butter should be less susceptible to lipid oxidation than the more unsaturated summer product but the reverse appears to be the case, probably owing to higher levels of pro-oxidants, for example Cu and Fe, in winter milk.

Although a ruminant's diet, especially if grass-based, is rich in polyunsaturated fatty acids (PUFA), these are hydrogenated by bacteria in the rumen and, consequently, ruminant milk fat contains very low levels of PUFAs, for example bovine milk fat contains approximately 2.4% $C_{18:2}$ compared to approximately 13% in human or porcine milk fat. PUFAs are considered to be nutritionally desirable and consequently there has been interest in increasing the PUFA content of bovine milk fat. This can be done by feeding encapsulated PUFA-rich lipids or crushed PUFA-rich oil seed to the animal. Increasing the PUFA content also reduces the melting point (MP) of the fat and makes butter produced from it more spreadable. However, the lower MP fat may have undesirable effects on the rheological properties of cheese, and PUFA-rich dairy products are very susceptible to lipid oxidation. Although the technical feasibility of increasing the PUFA content of milk fat by feeding protected PUFA-rich lipids to the cow has been demonstrated, it is not economical to do so in most cases. Blending milk fat with PUFA-rich or $C_{18:1}$-rich vegetable oil appears to be much more viable and is now widely practised commercially.

CONJUGATED LINOLEIC ACID

Linoleic acid (*cis, cis* 9, 12-octadecadienoic acid) is the principal essential fatty acid and has been the focus of nutritional research for many years. However, conjugated isomers of linoleic acid (CLA) have attracted very considerable attention recently (for review, see Bauman and Lock 2006). CLA is a mixture of eight positional and geometric isomers of linoleic acid, which have a number of health-promoting properties, including anti-carcinogenic and anti-atherogenic activities, reduction of the catabolic effects of immune stimulation and the ability to enhance growth and reduce body fat (see Parodi 1999, Yurawecz et al. 1999). Of the eight isomers of CLA, only the *cis*-9, *trans*-11 isomer is biologically active. This compound is effective at very low concentrations, 0.1 g/100 g diet.

Fat-containing foods of ruminant origin, especially milk and dairy products, are the principal sources of dietary CLA, which is produced as an intermediate during the biohydrogenation of linoleic acid by the rumen bacterium, *Butyrivibrio fibrisolvens.* Since CLA is formed from linoleic acid, it is not surprising that the CLA content of milk is affected by diet and season, being highest in summer when cows are on fresh pasture rich in PUFAs (Lock and Garnsworthy 2000, Lawless et al. 2000) and is higher in the fat of milk from cows on mountain pasture than on lowland pasture (Collomb et al. 2002). The concentration of CLA in milk fat can be increased five to seven folds by increasing the level of dietary linoleic acid, for example by duodenal infusion (Kraft et al. 2000) or by feeding a linoleic acid-rich oil, for example sunflower oil (Kelly et al. 1998)

A number of other lipids may have anticarcinogenic activity, for example sphingomyelin, butanoic acid and ether lipids, but little information is available on these to date (Parodi 1997, 1999)

STRUCTURE OF MILK TRIGLYCERIDES

Glycerol for milk lipid synthesis is obtained in part from hydrolysed blood lipids (free glycerol and monoglycerides), partly from glucose and a little from free blood glycerol. Synthesis of triglycerides within the cell is catalysed by enzymes located on the endoplasmic reticulum. Esterification of fatty acids is not random (Table 24.1). The concentrations of $C_{4:0}$ and $C_{18:1}$ appear to be rate-limiting because of the need to keep the lipid liquid at body temperature. Some notable features of the structure are as follows:

- Butanoic and hexanoic acids are esterified almost entirely, and octanoic and decanoic acids predominantly, at the *sn*-3 position.
- As the chain-length increases up to $C_{16:0}$, an increasing proportion is esterified at the *sn*-2 position; this is more marked for human than for bovine milk fat, especially in the case of palmitic acid ($C_{16:0}$).
- Stearic acid ($C_{18:0}$) is esterified mainly at *sn*-1.
- Unsaturated fatty acids are esterified mainly at the *sn*-1 and *sn*-3 positions, in roughly equal proportions.

The fatty acid distribution is significant from two viewpoints:

1. It affects the MP and hardness of the fat, which can be reduced by randomising the fatty acid distribution. Trans-esterification can be performed by treatment with $SnCl_2$ or enzymatically under certain conditions: increasing

Table 24.1. Composition of Fatty Acids (mol% of the Total) Esterified to Each Position of the Triacyl-*sn*-Glycerols in Bovine or Human Milk

Fatty Acid	Cow			Human		
	sn-1	*sn*-2	*sn*-3	*sn*-1	*sn*-2	*sn*-3
4:0	–	–	35.4	–	–	–
6:0	–	0.9	12.9	–	–	–
8:0	1.4	0.7	3.6	–	–	–
10:0	1.9	3.0	6.2	0.2	0.2	1.1
12:0	4.9	6.2	0.6	1.3	2.1	5.6
14:0	9.7	17.5	6.4	3.2	7.3	6.9
16:0	34.0	32.3	5.4	16.1	58.2	5.5
16:1	2.8	3.6	1.4	3.6	4.7	7.6
18:0	10.3	9.5	1.2	15.0	3.3	1.8
18:1	30.0	18.9	23.1	46.1	12.7	50.4
18:2	1.7	3.5	2.3	11.0	7.3	15.0
18:3	–	–	–	0.4	0.6	1.7

attention is being focused on the latter as an acceptable means of modifying the harness of butter.

2. Pancreatic and many other lipases are specific for the fatty acids at the *sn*-1 and *sn*-3 positions. Therefore, $C_{4:0}$–$C_{8:0}$ are released rapidly from milk fat; these are water-soluble and are readily absorbed from the intestine. Medium- and long-chain acids are absorbed more effectively as 2-monoglycerides than as fatty acids; this appears to be quite important for the digestion of lipids by human infants who have limited ability to digest lipids due to the absence of bile salts. Infants metabolise human milk fat more efficiently than bovine milk fat, apparently due to the very high proportion of $C_{16:0}$ esterified at *sn*-2 in the former. The effect of trans-esterification on the digestibility of milk fat by infants merits investigation.

Short-chain fatty acids ($C_{4:0}$–$C_{10:0}$) have a strong aroma and flavour and their release by indigenous lipoprotein lipase (LPL) and microbial lipases cause off-flavours in milk and many dairy products, referred to as hydrolytic rancidity.

RHEOLOGICAL PROPERTIES OF MILK FAT

The melting characteristics of ruminant milk fat are such that, at low temperatures (e.g., *ex*-refrigerator), it contains a high proportion of solid fat and has poor spreadability. The rheological properties of milk lipids may be modified by fractional crystallisation, for example an effective treatment involves removing the middle MP fraction and blending high- and low-MP fractions. Fractional crystallisation is expensive and is practised in industry to only a limited extent; in particular, securing profitable outlets for the middle-MP fraction is a major economic problem.

Alternatively, the rheological properties of milk fat may be modified by increasing the level of PUFAs through feeding cows with protected PUFA-rich lipids, but this practise is also expensive. The melting characteristics of blends of milk fat and veg-

etable oils can be easily varied by changing the proportions of the different fats and oils in the blend. This procedure is economical and is widely practised commercially; blending also increases the level of nutritionally desirable PUFAs. The rheological properties of milk fat-based spreads can also be improved by increasing the moisture content of the product; obviously, this is economical and nutritionally desirable in the sense that the caloric value is reduced, but the resultant product is less microbiologically stable than butter.

The melting characteristics and rheological properties of milk fat can also be modified by inter- and trans-esterification. Chemically-catalysed inter- and trans-esterification are not permitted in the food industry but enzymatic catalysis may be acceptable. Lipases capable of such modifications on a commercial scale are available but their use is rather limited. Enzymatic trans-esterification allows modification of the nutritional as well as the rheological properties of lipids. The nutritional and rheological properties of lipids can also be modified by the use of a desaturase that converts $C_{18:0}$ to $C_{18:1}$ (these enzymes are a subject of ongoing research, see hppt://bioinfo.pbi.nrc.ca/covello/r-fattyacid.html; and Meesapyodsuk et al. 2000). However, this type of enzyme does not seem to be available commercially yet.

MILK FAT AS AN EMULSION

An emulsion consists of two immiscible, mutually insoluble liquids, usually referred to as oil and water, in which one of the liquids is dispersed as small droplets (globules; the dispersed phase) in the other (the continuous phase). If the oil is the dispersed phase, the emulsion is referred to as an oil-in-water (O/W) emulsion; if water is the dispersed phase, the emulsion is referred to as a water-in-oil (W/O) emulsion. The dispersed phase is usually, but not necessarily, the phase present in the smaller amount. An emulsion is prepared by dispersing one phase into the other. Since the liquids are immiscible, they will remain discrete and separate if they differ in density, as is the case with lipids and water, the density of which are 0.9 and 1.0, respectively; the lipid globules will float to the surface and coalesce. Coalescence is prevented by adding a compound which reduces the interfacial tension, γ, between the phases. Compounds capable of doing this have an amphipathic structure, that is hydrophobic and hydrophilic regions, for example phospholipids, monoglycerides, diglycerides, proteins, soaps and numerous synthetic compounds, and are known as emulsifiers or detergents. The emulsifier forms a layer on the surface of the globules with its hydrophobic region penetrating the oil phase and its hydrophilic region in the aqueous phase. An emulsion thus stabilised will cream if left undisturbed, but the globules remain discrete and can be redispersed readily by gentle agitation.

In milk, the lipids exist as an O/W emulsion in which the globules range in size from approximately 0.1 to 20 μm, with a mean of 3–4 μm. The mean size of the fat globules is higher in high-fat milk than in low-fat milk, for example Jersey compared to Friesian, and decreases with advancing lactation. Consequently, the separation of fat from milk is less efficient in winter than in summer, especially when milk production is seasonal, and it

may not be possible to meet the upper limit for fat content in some products, for example casein, during certain periods.

STABILITY OF MILK FAT GLOBULES

In milk, the emulsifier is the MFGM. On the inner side of the MFGM is a layer of unstructured lipoproteins, acquired within the secretory cells as the triglycerides move from the site of synthesis in the rough endoplasmic reticulum (RER) in the basal region of the cell towards the apical membrane. The fat globules are excreted from the cells by exocytosis, that is they are pushed through and become surrounded by the apical cell membrane. Milk proteins and lactose are excreted from the cell by the reverse process: the proteins are synthesised in the RER and are transported to the Golgi region, where the synthesis of lactose occurs under the control of α-La. The milk proteins and lactose are encapsulated in Golgi membrane; the vesicles move towards, and fuse with, the apical cell membrane, open and discharge their contents into the alveolar lumen, leaving the vesicle (Golgi) membrane as part of the apical membrane, thereby replacing the membrane lost on the excretion of fat globules. Thus, the outer layer of the MFGM is composed of a trilaminar membrane, consisting of phospholipids and proteins, with a fluid mosaic structure.

Many of the proteins of the MFGM are strongly hydrophobic and difficult to isolate and characterise. Modern proteomic methods have shown that the MFGM contains about 100 proteins, of which the following are the principal and have been isolated and characterised: butyrophilin (BTN), xanthine dehydrogenase (XDH), acidophilin, PAS (periodic acid Schiff staining) 6/7, CD (cluster of differentiation) 36, fatty acid-binding protein, mucins 1 and 15 (MUC). BTN is a trans-membrane protein that complexes with XDH (located on the inner face of the membrane) that initiates the blebbing of the fat globule through the apical membrane of the cell (in this role, XDH does not act as an enzyme). MUC1, MUC 15, CD 36 and PAS6/7 are heavily glycosylated and are located mainly on the outer surface of the membrane, increasing its hydrophilicity. Very considerable progress has been made on the proteins during the past 10 years, which has been reviewed by Mather (2000, 2011) and Keenan and Mather (2006). In human and equine milk, the MUC form long (up to 50 μm) filaments that are lost easily; the filaments probably retard the passage of lipids through the small intestine, thereby improving digestibility, and prevent the adhesion of pathogens.

The MFGM contains many enzymes that originate mainly from the Golgi apparatus: in fact, most of the indigenous enzymes in milk are concentrated in the MFGM, notable exceptions being plasmin and LPL that are associated with the casein micelles. The trilaminar membrane is unstable and is shed during storage, and especially during agitation, into the aqueous phase, where it forms microsomes.

The stability of the MFGM is critical for many aspects of the milk fat system:

- The existence of milk as an emulsion depends on the effectiveness of the MFGM.

- Damage to the MFGM leads to the formation of non-globular (free) fat, which may be evident as 'oiling-off' on tea or coffee, cream plug or age thickening. An elevated level of free fat in whole milk powder reduces its wettability. Problems related to, or arising from, free fat are more serious in winter than in summer, probably due to the reduced stability of the MFGM. Homogenisation, which replaces the natural MFGM by a layer of proteins from the skim milk phase, principally caseins, eliminates problems caused by free fat.

- The MFGM protects the lipids in the core of the globule against lipolysis by LPL in the skim milk (adsorbed on the casein micelles). The MFGM may be damaged by agitation, foaming, freezing, for example on bulk tank walls, and especially by homogenization, allowing access for LPL to the core lipids and leading to lipolysis and hydrolytic rancidity. This is potentially a major problem in the dairy industry unless milking machines, especially pipeline milking installations, are properly installed and serviced.

- The MFGM appears to be less stable in winter/late lactation than in summer/mid lactation; therefore, hydrolytic rancidity is more likely to be a problem in winter than in summer. An aggravating factor is that less milk is usually produced in winter than in summer, especially in seasonal milk production systems, which leads to greater agitation and air incorporation during milking and, consequently, a greater risk of damage to the MFGM.

CREAMING

Since the specific gravity of lipids and skim milk is 0.9 and 1.036, respectively, the fat globules in milk held under quiescent conditions will rise to the surface under the influence of gravity, a process referred to as creaming. The rate of creaming, V, of fat globules is given by Stoke's equation:

$$V = \frac{2r^2(\rho^1 - \rho^2)g}{9\eta}$$

where
$r =$ radius of the fat globules
$\rho^1 =$ specific gravity of skim milk
$\rho^2 =$ specific gravity of the fat globules
$g =$ acceleration due to gravity
$\eta =$ viscosity of milk

The typical values of r, ρ^1, ρ^2 and η suggest that a cream layer should form in milk after approximately 60 hours but milk creams in approximately 30 minutes. The rapid rate of creaming is due to the strong tendency of the fat globules to agglutinate (stick together) due to the action of indigenous immunoglobulin (Ig) M, which precipitates onto the fat globules when milk is cooled (hence, they are called cryoglobulins). Considering the effect of globule size (r) on the rate of creaming, large globules rise faster than smaller ones and collide with, and adhere to, smaller globules, an effect promoted by cryoglobulins. Owing to the larger value of r, the clusters of globules rise faster than individual globules, and therefore the creaming process

accelerates as the globules rise and clump. Ovine, caprine and buffalo milk do not contain cryoglobulins and therefore cream much more slowly than bovine milk.

In the past, creaming was a very important physicochemical property of milk:

- The cream layer served as an index of fat content and hence of quality to the consumer.
- Creaming was the traditional method for preparing fat (cream) from milk for use in the manufacture of butter. Its significance in this respect declined after the development of the mechanical separator by Gustav de Laval in 1878 but natural creaming is still used to adjust the fat content of milk for some cheese varieties, for example Parmigiano-Reggiano. A high proportion (∼90%) of the bacteria in milk become occluded in the clusters of fat globules.

Homogenisation of Milk

Today, creaming is of little general significance. In most cases, its effect is negative and for most dairy products, milk is homogenised, that is subjected to a high-shear pressure that reduces the size of the fat globules (average diameter <1 μm), increases the fat surface area (four to six fold), replaces the natural MFGM by a layer of caseins and denatures cryoglobulins, hence preventing the agglutination of globules.

Homogenization of milk is usually performed using a valve homogeniser (developed by August Gaulin in 1899), in which milk is forced at a pressure of approximately 20 MPa against a spring-loaded valve. The residence time in the valve is very short and many newly formed globules share emulsifier (probably casein micelles), leading to the formation of clusters that will cream rapidly and increase the viscosity of the system. The clusters are dispersed by a second homogenisation at approximately 3.5 MPa. Recently, a high-pressure homogeniser, operating at a pressure up to 300 MPa, has been developed. This type of homogeniser gives a very narrow distribution of fat globules, resulting in improved product quality.

Homogenisation has several very significant effects on the properties of milk:

- If properly executed, creaming is delayed indefinitely due to the reduced size of the fat globules, the denaturation of cryoglobulins and the increased density of the fat globules, due to the layer of adsorbed casein on the surface.
- Susceptibility to hydrolytic rancidity is markedly increased because indigenous LPL has ready access to the triglycerides; consequently, milk must be heated under conditions sufficiently severe to inactivate LPL before (usually) or immediately after homogenisation.
- Susceptibility to oxidative rancidity is reduced because prooxidants in the MFGM, for example metals and xanthine oxidase, are distributed throughout the milk.
- The whiteness of milk is increased, due to the greater number of light-scattering particles.
- The strength and syneretic properties of rennet-coagulated milk gels for cheese manufacture are reduced; hence, cheese with a higher moisture content is obtained. Con-

sequently, milk for cheese manufacture is not normally homogenised; an exception is reduced-fat cheese, in which a higher moisture content improves texture.
- The heat stability of whole milk and cream is reduced, the magnitude of the effect increasing directly with fat content and homogenisation pressure; homogenisation has no effect on the heat stability of skimmed milk.
- The viscosity of whole milk and cream is increased by single-stage homogenisation due to the clustering of newly formed fat globules, caused by sharing of casein micelles; the clumps of globules are dispersed by a second homogenisation stage at a lower pressure, which may be omitted if an increased viscosity is desired.

Lipid Oxidation

The chemical oxidation of lipids is a major cause of instability in dairy products (and many other foods). Lipid oxidation is a free radical, autocatalytic process principally involving the methylene group between a pair of double bonds in PUFAs; oxygen is a primary reactant (see O'Brien and O'Connor 2011). The process is initiated and/or catalysed by polyvalent metals, especially Cu and Fe, ultraviolet (UV) light, ionising radiation or enzymes, such as lipoxygenase in the case of plant oils, and xanthine oxidase, which is a major component of the MFGM, in milk. The principal end-products are unsaturated carbonyls, which cause major flavour defects; the reaction intermediates, that is fatty acid free radicals, peroxy free radicals and hydroperoxides, have no flavour. Polymerisation of free radicals and other species leads to the formation of pigmented products and to an increase in viscosity but it is unlikely that polymerisation-related problems occur to a significant extent in dairy products.

Lipid oxidation can be prevented or controlled by the following:

- Avoiding metal contamination at all stages of processing through the use of stainless steel equipment.
- Avoiding exposure to UV light by using opaque packing (foil or paper).
- Packaging under an inert atmosphere, usually N_2.
- Use of O_2 or free-radical scavengers, for example glucose oxidase and superoxide dismutase (an indigenous enzyme in milk), respectively.
- Use of antioxidants which break the free radical chain reaction; synthetic antioxidants are not permitted in dairy products but the level of natural antioxidants, for example tocopherols (vitamin E), in milk may be increased by supplementing the animal's feed. Polyphenols are very effective antioxidants; their direct addition to dairy products is not permitted but it may also be possible to increase their concentration in milk by supplementing the animal's feed. Antioxidants are compounds which readily supply a H· to fatty acid and peroxy radicals, leaving a stable oxidised radical. Many antioxidants are polyphenols, which give up a H· and are converted to a quinone; examples are tocopherols (vitamin E) and catechins. At low concentrations, ascorbic acid is a good antioxidant but at high concentrations it

functions as a pro-oxidant, apparently as a complex with Cu. Sulphydryl groups of proteins are also effective antioxidants; cream for butter making is usually heated to a high temperature to denature proteins and expose and activate sulphydryl groups.

Fat-Soluble Vitamins

Since the fat-soluble vitamins (A, D, E and K) in milk are derived from the animal's diet, large seasonal variations can be expected in their concentration in milk. The breed of cow also has a significant effect on the concentration of fat-soluble vitamins in milk; high-fat milk (Jersey and Guernsey) has a higher content of these vitamins than Friesian or Holstein milk. Variations in the concentrations of fat-soluble vitamins in milk have a number of consequences:

- Nutritionally, milk contributes a substantial portion of the RDA (recommended daily allowance) for these vitamins to Western diets; it is common practice to fortify milk and butter with vitamins A and D.
- The yellow-orange colour of high-fat dairy products depends on the concentrations of carotenoids and vitamin A present, and hence on the diet of the animal. New Zealand butter is much more highly coloured than Irish butter, which in turn is much more yellow than American or German products. The differences are due in part to the greater dependence of milk production in New Zealand and Ireland on pasture and to the higher proportion of carotenoid-rich clover in New Zealand pasture and the higher proportion of Jersey cows in New Zealand herds.
- Goats, sheep and buffalo do not transfer carotenoids to their milk, which is, consequently, whiter than bovine milk. Products produced from these milks are whiter than corresponding products made from bovine milk. The darker colour of the latter may be unattractive to consumers accustomed to caprine or ovine milk products. If necessary, the carotenoids in bovine milk may be bleached (by benzoyl peroxide) or masked (by chlorophyll or T_iO_2).
- Vitamin E (tocopherols) is a potent antioxidant and contributes to the oxidative stability of dairy products. The tocopherol content of milk and meat can be readily increased by supplementing the animal's diet with tocopherols, which is sometimes practised.

MILK PROTEINS

Introduction

Technologically, the proteins of milk are its most important constituents. They play important, even essential, roles in all dairy products except butter and anhydrous milk fat. The roles played by milk proteins include the following:

- *Nutritional*: All milk proteins.
- *Physiological*: Igs, lactoferrin (Lf), lactoperoxidase, vitamin-binding proteins, protein-derived biologically-active peptides.

- *Physico-chemical*:
  - *Gelation*. Enzymatically, acid- or thermally induced gelation in all cheeses, fermented milks, whey protein concentrates and isolates.
  - *Heat stability*: All thermally processed dairy products,
  - *Surface activity*: Caseinates, whey protein concentrates and isolates.
  - *Rheological*: All protein-containing dairy products.
  - *Water sorption*: Most dairy products, comminuted meat products.

Milk proteins have been studied extensively and are very well characterised at molecular and functional levels (for reviews, see Fox and McSweeney 2003).

Heterogeneity of Milk Proteins

It has been known since 1830 that milk contains two types of protein which can be separated by acidification, to what we now know is pH 4.6. The proteins insoluble at pH 4.6 are called caseins and represent approximately 78% of the total nitrogen in bovine milk; the soluble proteins are called whey or serum proteins. As early as 1885, it was shown that there are two types of whey protein, globulins and albumins, which were thought to be transferred directly from the blood (the proteins of blood and whey have generally similar physico-chemical properties and are classified as albumins and globulins). Initially, the term casein was not restricted to the acid-insoluble proteins in milk but was used to describe all acid-insoluble proteins; however, it was recognised at an early stage that the caseins are unique milk-specific proteins.

The casein fraction of milk protein was considered initially to be homogeneous but from 1918 onwards, evidence began to accumulate that it is heterogeneous. Through the application of free boundary electrophoresis (FBE) in the 1930s and especially zone electrophoresis in starch or polyacrylamide gels (SGE, PAGE) containing urea and a reducing agent in the 1960s, it has been shown that casein is in fact very heterogeneous. Bovine casein consists of four families of caseins: α_{s1}-, α_{s2}- β- and κ-, which represent about 38%, 10%, 36% and 12%, respectively, of whole casein. Urea-PAGE showed that each of the casein families exhibits micro-heterogeneity due to:

- genetic polymorphism, usually involving substitution of one or two amino acids;
- variations in the degree of phosphorylation;
- variations in the degree of glycosylation of κ-casein;
- inter-molecular disulphide bond formation in α_{s2}- and κ-caseins;
- limited proteolysis, especially of β- and α_{s2}-caseins, by plasmin; the resulting peptides include the γ- and λ-caseins and proteose peptones.

In the 1930s, FBE showed that both the globulin and albumin fractions of whey protein are heterogeneous and, in the 1950s, the principal constituents were isolated and characterised. It is now known that the whey protein fraction of bovine milk comprises four main proteins: β-lactoglobulin (β-Lg), α-La, Igs and

blood serum albumin (BSA), which represent about 40%, 20%, 10% and 10%, respectively, of the total whey protein in mature milk. The remaining 10% is mainly non-protein nitrogen and trace amounts of several proteins, including *ca.* 60 indigenous. Sixty indigenous enzymes. About 1% of total milk protein is part of the MFGM, including many enzymes. β-Lg and α-La are synthesised in the mammary gland and are milk-specific; they exhibit genetic polymorphism (in fact, the genetic polymorphism of milk proteins was first demonstrated for β-Lg in 1956). BSA, most of the Ig (i.e., IgG) and most of the minor proteins are transferred from the blood.

Methods for the isolation of the individual proteins were developed and gradually improved during the period 1950–1970, so that by around 1970 all the principal milk proteins had been purified to homogeneity.

The concentration of total protein in milk is affected by most of the factors that affect the concentration of fat, that is breed, individuality, nutritional status, health and stage of lactation but, with the exception of the last, the magnitude of most effects is less than in the case of milk fat. The concentration of protein in milk decreases very markedly during the first few days *post-partum*, mainly due to the decrease in Ig from approximately 10% in the first colostrum to 0.1% within about 1 week. The concentration of total protein continues to decline more slowly thereafter, to a minimum after about 4 weeks and then increases until the end of lactation. Data on variations in the groups of proteins throughout lactation have been published (see Mehra et al. 1999) but there are few data on variations in the concentrations of the individual principal proteins.

MOLECULAR PROPERTIES OF MILK PROTEINS

The six principal milk-specific proteins have been isolated and are very well characterised at the molecular level; their chemical composition is summarised in Table 24.2. The most notable features of the principal milk-specific proteins are discussed later.

They are quite small molecules, approximately 15–25 kDa. All the caseins are phosphorylated but to different and variable degrees, 1–13 mol P/mol protein; the phosphate groups are esterified as monoesters of serine residues. The primary struc-

tures of the caseins have a rather uneven distribution of polar and non-polar residues along their sequences. Clustering of the phosphoseryl residues is particularly marked, resulting in strong anionic patches in α_{s1}-, α_{s2}- and β-caseins. κ-Casein does not have a phosphoseryl cluster but the N-terminal two-thirds of the molecule is quite hydrophobic while its C-terminal is relatively hydrophilic – it contains no aromatic and no cationic residues. These features give the caseins an amphipathic structure, making them very surface-active, with good emulsifying and foaming properties. The amphipathic structure of κ-casein is particularly significant and is largely responsible for its micelle-stabilising properties. The distribution of amino acids in β-Lg and α-La is quite random.

The two principal caseins, α_{s1}- and β-caseins, are devoid of cysteine or cystine residues; the two minor caseins, α_{s2}- and κ-caseins, contain two inter-molecular disulphide bonds. β-Lg contains two intra-molecular disulphide bonds and one sulphydryl group that is buried and unreactive in the native protein but becomes exposed and reactive when the molecule is denatured; it reacts *via* sulphydryl-disulphide interactions with other proteins, especially κ-casein, with major consequences for many important properties of the milk protein system, especially heat stability and cheese making properties. α-La has four intra-molecular disulphide bonds.

All the caseins, especially β-casein, contain a high level of proline (in β-casein, 17 of the 209 residues are proline), which disrupts α- and β-structures; consequently, the caseins are rather unstructured molecules and are readily susceptible to proteolysis, which is as would be expected for proteins the putative function of which is as a source of amino acids for the neonate. However, theoretical calculations suggest that the caseins may have a considerable level of secondary and tertiary structure; to explain the differences between the experimental and theoretical indices of higher structures, it has been suggested that the caseins are very mobile, flexible, rheomorphic molecules (i.e., the casein molecules, in solution, are sufficiently flexible to adopt structures that are dictated by their environment; Holt and Sawyer 1993). In contrast, the whey proteins are highly compact and structured, with high levels of α-helices, β-sheets and β-turns. In β-Lg, the β-sheets are in an anti-parallel arrangement and form a β-barrel calyx.

Table 24.2. Characteristics of the Principal Proteins in Bovine Milk

| Protein | Molecular Weight | Amino Acid Residues | | | Phosphate Groups | Concentration (g/L) | Genetic Variants |
		Total	Proline	Cysteine			
α_{s1}-casein	23,164	199	17	0	8	10.0	A, B, C, D, E, F, G, H
α_{s2}-casein	25,388	207	10	2	10–13	2.6	A, B, C, D
β-casein	23,983	209	35	0	5	9.3	A[1], A[2]. A[3], B, C, D, E, F, G
κ-casein	19,038	169	20	2	1	3.3	A, B, C, D, E, F[S], F[I], G[S], H, I, J
β-lactoglobulin	18,277	162	8	5	0	3.2	A, B, C, D, E, F, G, H, I, J
α-lactalbumin	14,175	123	2	8	0	1.2	A, B, C

Source: Adapted from Fox 2003.

The caseins are often regarded as very hydrophobic proteins but they are not particularly so; however, they do have a high surface hydrophobicity, owing to their open structures. Because of their hydrophobic patches they have a high propensity to yield bitter hydrolysates, even in cheese that undergoes relatively little proteolysis. In contrast, the highly structured whey proteins are very resistant to proteolysis in the native state and may traverse the intestinal tract of the neonate intact.

About 60% of κ-casein molecules are glycosylated. The sugar moieties present are galactose, galactosamine and N-acetylneuraminic acid (sialic acid), which occur as trisaccharides or tetrasaccharides. The oligosaccharides are attached to the polypeptide *via* threonine residues in the *C*-terminal region of the molecule and vary from 0 to 4 mol/mol of protein.

Probably because of their rather open structures, the caseins are extremely heat stable, for example sodium caseinate can be heated at 140°C for 1 hour without obvious physical effects. The more highly structured whey proteins are comparatively heat-labile, although compared to many other globular proteins, they are quite heat-stable; they are completely denatured on heating at 90°C for 10 minutes.

Under the ionic conditions in milk, α-La exists as monomers of molecular weight (MW) approximately 14.7 kDa. β-Lg exists as dimers (MW $\sim$36 kDa) in the pH range 5.5–7.5; at pH values <3.5 or >7.5, it exists as monomers, while at pH 3.5–5.5, it exists as octamers. The caseins have a very strong tendency to associate. Even in sodium caseinate, the most soluble form of whole casein, the proteins exist mainly as decamers or larger aggregates at 20°C. At low concentrations, for example <0.6%, at 4°C, β-casein exists as monomers but associates to form micelles if the concentration or temperature is increased. In the presence of Ca, for example, calcium caseinate, casein forms large aggregates of several million Daltons. In milk, the caseins exist as very complex structures, known as casein micelles, which are described in Section 'Casein Micelles'.

The function of the caseins appears to be to supply amino acids to the neonate. They have no biological function *stricto sensu* but their Ca-binding properties enable a high concentration of calcium phosphate to be carried in milk in a 'soluble' form; the concentration of calcium phosphate far exceeds its solubility and, without the 'solubilising' influence of casein, would precipitate in the ducts of the mammary gland and cause atopic milk stones.

β-Lg has a hydrophobic pocket within which it can bind small hydrophobic molecules. It binds and protects retinol *in vitro* and perhaps functions as a retinol carrier *in vivo*. In the intestine, it exchanges retinol with a retinol-binding protein. It also binds fatty acids and thereby stimulates lipase; this is perhaps its principal biological function. β-Lg is a member of the lipocalin family, which now includes 14 proteins (for review see Akerstrom et al. 2000); all members of the lipocalin family have some form of binding function.

α-La is a metalloprotein; it binds one Ca atom per molecule in a peptide loop containing four aspartic acid residues. The apo-protein is quite heat-labile but the metalloprotein is rather heat-stable; when studied by differential scanning calorimetry, α-La is in fact observed to be quite heat-labile. The metallo-protein renatures on cooling, whereas the apo-protein does not. The difference in heat stability between the halo- and apo-protein may be exploited in the isolation of α-La on a large (i.e., potentially industrial) scale.

As discussed in Section 'Lactose', α-La is an enzyme modifier protein in the lactose synthesis pathway; it makes UDP-galactosyl transferase highly specific for glucose as an acceptor for galactose, resulting in the synthesis of lactose.

INTERSPECIES COMPARISON OF MILK PROTEINS

The milk of all species that have been studies contain caseins and whey proteins, but the protein systems differ in detail:

- The total concentration of protein ranges from approximately 1% in human milk and that of the other great apes to approximately 20% for lagomorphs; the protein content is directly related to the growth rate of the neonate.
- The ratio of casein to whey proteins ranges from approximately 80:20 in bovine, buffalo, ovine and caprine milk to approximately 30:70 for human milk.
- The types and proportions of the caseins and whey proteins show considerable inter-species differences. The milk of all species studied seems to contain α-, β- and κ- caseins but human milk and that of some other primates contains very little α-casein and equine milk contains little κ-casein. The milk of humans and that of many others, but not all, primates and rodents lacks β-Lg. The principal protein in human milk is α-La but the milk of some seals lacks this protein. The milk of some species contains a protein called acid whey protein, which is absent from the milk of many species, including cow, buffalo, sheep and goat. There are particularly large inter-species differences with respect to many minor proteins, including enzymes.
- All individual milk proteins show inter-species differences with respect to amino acid composition and perhaps other features. An interspecies comparison of the principal lactoproteins of several species has been made by Martin et al. (2003, 2011).

CASEIN MICELLES

Three of the caseins, α_{s1}-, α_{s2}- and β-, which together represent approximately 85% of total casein, are precipitated by calcium at concentrations >6 mM at temperatures >20°C. Since milk contains approximately 30 mmol/L Ca, it would be expected that most of the caseins would precipitate in milk. However, κ-casein is soluble at high concentrations of Ca and it reacts with and stabilises the Ca-sensitive caseins through the formation of casein micelles.

Since the stability, or perhaps instability, of the casein micelles is responsible for many of the unique properties and processing characteristics of milk, their structure and properties have been studied intensively. It has been known for nearly 200 years that the casein in milk exists as large colloidal particles which are retained by porcelain-Chamberlain filters. During the early part of the twentieth century, there was interest in explaining the rennet

coagulation of milk and hence in the structure and properties of the Ca-caseinate particles (for review, see Fox and Kelly 2003, Fox and McSweeney 2003). The term casein micelle appears to have been first used by Beau (1921). The idea that the rennet-induced coagulation of milk is due to the destruction of a protective colloid (Schütz colloid) dates from the 1920s; initially, it was suggested that the whey proteins were the 'protective colloid'. The true nature of the protective colloid, the structure of the casein micelle and the mechanism of rennet coagulation did not become apparent until the pioneering work on the identification, isolation and characterisation of κ-casein by Waugh and von Hippel (1956). Since then, the structure and properties of the casein micelle have been studied intensively. The evolution of views on the structure of the casein micelle was described by Fox and Kelly (2003), Horne (2003, 2011) and Fox and Brodkorb (2008). Current knowledge on the composition, structure and properties of the casein micelle and the key features thereof are summarised later.

The micelles are spherical colloidal particles, with a mean diameter of approximately 120 nm (range, 50–600 nm). They have a mean particle mass of approximately 10^8 Da, that is there are about 5000 casein molecules (20,000–25,000 Da each) in an average micelle. On a dry weight basis, the micelles contain approximately 94% protein and approximately 6% non-protein species, mainly calcium and phosphate, with smaller amounts of Mg and citrate and traces of other metals; these are collectively called colloidal (or micellar) calcium phosphate (CCP or MCP). Under the conditions that exist in milk, the micelles are hydrated to the extent of approximately 2 g H_2O/g protein. There are approximately 10^{15} micelles/mL milk, with a total surface area of approximately 5×10^4 cm^2; the micelles are about 240 nm apart. Owing to their very large surface area, the surface properties of the micelles are of major significance and because they are quite closely packed, even in unconcentrated milk, they collide frequently due to Brownian, thermal and mechanical motion.

The casein micelles scatter light; the white appearance of milk is due mainly to light scattering by the micelles, with a contribution from the fat globules. The micelles are generally stable to most processes and conditions to which milk is normally subjected and may be reconstituted from spray-dried or freeze-dried milk without major changes in their properties. Freezing milk destabilises the micelles, due to a decrease in pH and an increase in $[Ca^{2+}]$. On very severe heating, for example at 140°C, the micelles shatter initially, then aggregate and eventually, after approximately 20 minutes, the system coagulates (see Chapter 25)

The micelles can be sedimented by centrifugation; approximately 50% are sedimented by centrifugation at 20,000 × g for 30 minute and approximately 95% by 100,000 × g for 60 minute. The pelleted micelles can be redispersed by agitation, for example by ultrasonication, in natural or synthetic milk ultrafiltrate; the properties of the redispersed micelles are not significantly different from those of native micelles.

The casein micelles are not affected by regular ($\sim$20 MPa) or high-pressure (up to 250 MPa) homogenisation (Hayes and Kelly 2003). The average size is increased by high-pressure

treatment at 200 MPa, but they are disrupted (i.e., average size reduced by $\sim$50%) by treatment at a somewhat higher pressure, that is $\geq$400 MPa (Huppertz et al. 2002, 2004).

The micro-structure of the casein micelle has been the subject of considerable research during the past 40 years, that is since the discovery and isolation of the micelle-stabilising protein, κ-casein; however, there is still a lack of general consensus. Numerous models have been proposed, the most widely supported initially was the sub-micelle model, first proposed by Morr (1967) and refined several times since (Fox and Kelly 2003, Horne 2003, 2011, Fox and Brodkorb 2008). Essentially, this model proposes that the micelle is built up from sub-micelles (MW $\sim$5×10^6 Da) held together by CCP and surrounded and stabilised by a surface layer, approximately 7 nm thick, rich in κ-casein but also containing some of the other caseins (Fig. 24.3A). It is proposed that the hydrophilic C-terminal region of κ-casein protrudes from the surface, creating a hairy layer around the micelle and stabilising it through a zeta potential of ca −20 mV and by steric stabilisation. The principal direct experimental evidence for this model is provided by electron microscopy, which indicates a non-uniform electron density; this has been interpreted as indicating sub-micelles.

However, several authors have expressed reservations about the sub-unit model and three alternative models have been proposed. Visser (1992) suggested that the micelles are spherical aggregates of casein molecules randomly aggregated and held together partly by salt bridges in the form of amorphous calcium phosphate and partly by other forces, for example hydrophobic interactions, with a surface layer of κ-casein. Holt (1992) proposed that the Ca-sensitive caseins are linked by micro-crystals of CCP and surrounded by a layer of κ-casein, with its C-terminal region protruding from the surface (Fig. 24.3B). In the dual-binding model of Horne (2003, 2011), it is proposed that individual casein molecules interact via hydrophobic regions in their primary structures, leaving the hydrophilic regions free and with the hydrophilic C-terminal region of κ-casein protruding into the aqueous phase (Fig. 24.3C). Thus, the key structural features of the sub-micelle model are retained in the three alternatives, that is the integrating role of CCP and a κ-casein-rich surface layer.

The micelles disintegrate:

- when the CCP is removed, for example by acidification to pH 4.6 and dialysis in the cold against bulk milk, or by addition of trisodium citrate, also followed by dialysis; removal of >60% of the CCP results in disintegration of the micelles;
- on raising the pH to approximately 9.0, which does not solubilise the CCP and presumably causes disintegration by increasing the net negative charge;
- on adding urea to >5 M, which suggests that hydrogen and/or hydrophobic bonds are important for micelle integrity.

The micelles are precipitated by ethanol or other low MW alcohols at levels of $\geq$ approximately 35% at 20°C. However, if the temperature is increased to $\geq$70°C, surprisingly, the precipitated casein dissolves and the solution becomes quite clear, indicating

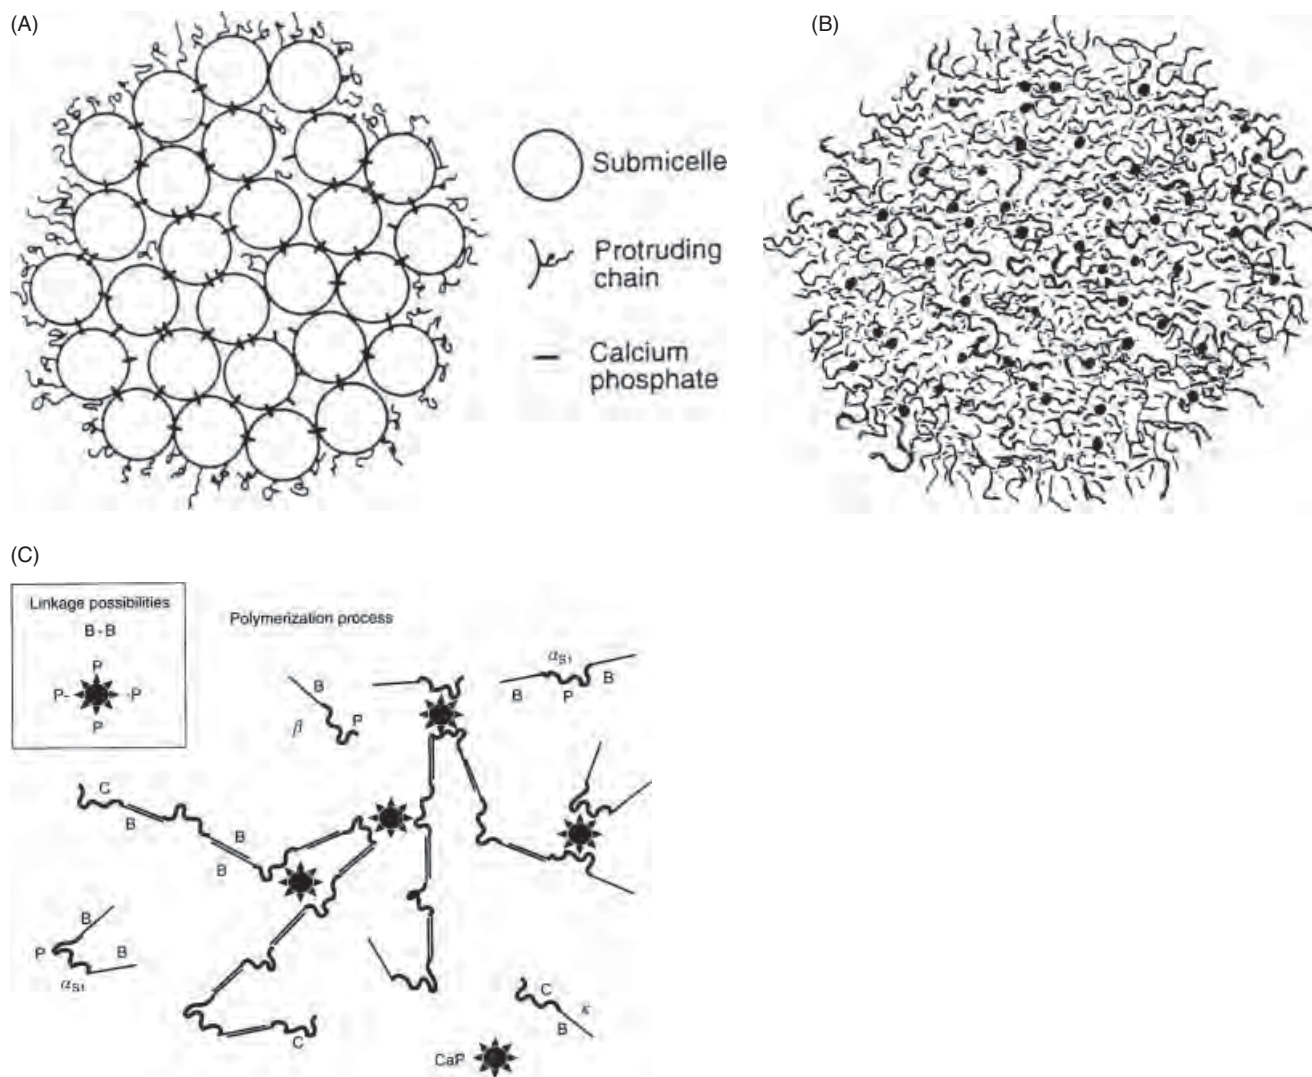

Figure 24.3. Models of casein micelle structure: (**A**) the submicelle model of Walstra (1999); (**B**) the Holt model (from Fox and McSweeney 1998); (**C**) the dual binding model, showing interactions between α_{s1}-, β- and κ-caseins (Horne 2003).

dissociation of the micelles (O'Connell et al. 2001a, b). Micelle-like particles reform on cooling and form a gel at ∼4°C. It is not known if the sub-particles formed by any of these treatments correspond to casein sub-micelles.

The turbidity of skim milk increases on addition of SDS up to 21mM, at which concentration a gel is formed; however, at ≥28 mM (∼0.8%, w/v) the micelles disperse (see Lefebvre-Cases et al. 2001a, b).

There have been few studies on variations in micelle size throughout lactation and these have failed to show consistent trends. No studies on variability in the micro-structure of the casein micelle have been published. We are not aware of studies on the effect of the nutritional or health status of the animal on the structure of the casein micelles, although their stability and behaviour are strongly dependent on pH, milk salts and whey proteins, all of which are affected by the health and nutritional status of the cow.

The milk of all species that have been studied is white, presumably due to light scattering by the casein micelles. However, the micelles of only a few species have been studied in detail; electron microscopy indicates that the micelles of all species are spherical and range in size from approximately 50 nm in human milk to ∼600 nm in equine milk. Some of the large micelles in equine milk settle out under gravity or low centrifugal forces; the large micelles reflect the low level of κ-casein in equine milk. The milk of most species is supersaturated with calcium phosphate and the insoluble part (CCP) is present in the casein micelles, in which it acts as a cementing material; the micelles disintegrate when the CCP is removed. Human milk lacks CCP and its micelles have a rather porous structure.

Minor Proteins

In addition to the caseins and the two principal whey proteins, milk contains several proteins at low or trace levels. Many of these minor proteins are biologically active (see Schrezenmeir et al. 2000); some are regarded as highly significant and have attracted considerable attention as nutraceuticals. When ways of increasing the value of milk proteins are discussed, the focus is usually on these minor proteins but they are, in fact, of little economic value to the overall dairy industry. They are found mainly in the whey but some are also located in the fat globule membrane. Reviews on the minor proteins include Fox and Flynn (1992), Haggarty (2003) and Wynn (2011).

Immunoglobulins

Bovine colostrum contains approximately 10% (w/v) Igs, but this level declines rapidly to approximately 0.1% about 5 days *post-partum*. IgG1 is the principal Ig in bovine, caprine or ovine milk, with lesser amounts of IgG2, IgA and IgM; IgA is the principal Ig in human milk. The cow, sheep and goat do not transfer Ig to the foetus *in utero* and the neonate is born without Ig in its blood serum; consequently, it is very susceptible to bacterial infection, with a very high risk of mortality. The young of these species can absorb Ig from the intestine for several days after birth and thereby acquire passive immunity until they synthesise its own Ig, within a few weeks of birth. The human mother transfers Ig *in utero* and the offspring is born with a broad spectrum of antibodies. Although the human baby cannot absorb Ig from the intestine, the ingestion of colostrum is still very important because the Igs it contains prevent intestinal infection. Some species, for example the horse, transfer Ig both *in utero* and *via* colostrum.

The modern dairy cow produces colostrum far in excess of the requirements of her calf. Therefore, surplus colostrum is available for the recovery of Ig and other nutraceuticals (Paakanen and Aalto 1997, Marnila and Korhonen 2011). There is also considerable interest in hyper-immunising cows against certain human pathogens, for example rota virus, for the production of antibody-rich milk for human consumption, especially by infants; the Ig could be isolated from the milk and presented as a 'pharmaceutical' or consumed directly in the milk.

Blood Serum Albumin

About 1–2% of the protein in bovine milk is BSA, which enters from the blood by leakage through inter-cellular junctions. As befits its physiological importance, BSA is very well characterised (see Carter and Ho 1994). BSA has no known biological function in milk and, considering its very low concentration, it probably has no technological significance either.

Metal-Binding Proteins

Milk contains several metal-binding proteins: the caseins (which bind Ca, Mg, PO_4) are quantitatively the most important; others are α-La (Ca), xanthine oxidase (Fe, Mo), alkaline phosphatase (Zn, Mg), lactoperoxidase (Fe), catalase (Fe), ceruloplasmin (Cu), glutathione peroxidase (Se), Lf (Fe) and seroferrin (Fe).

Lf, a non-haem iron-binding glycoprotein (see Lonnerdal 2003, Korhonen and Marnila 2011), is a member of a family of iron-binding proteins, which includes seroferrin and ovotransferrin (conalbumin). It is present in several body fluids, including saliva, tears, sweat and semen. Lf has several potential biological functions; it improves the bioavailability of Fe, is bacteriostatic (by sequestering Fe and making it unavailable to intestinal bacteria), and has antioxidant, antiviral, anti-inflammatory, immunomodulatory and anti-carcinogenic activity. Human milk contains a much higher level of Lf (~20% of total N) than bovine milk and therefore there is interest in fortifying bovine milk-based infant formula with Lf. The pH of Lf is ~9.0, that is it is cationic at the pH of milk, whereas most milk proteins are anionic, and can be isolated on an industrial scale by adsorption on a cation-exchange resin. Hydrolysis of Lf by pepsin yields peptides called lactoferricins, which are more bacteriostatic than Lf and their activity is independent of iron status. Bovine milk also contains a low level of serum transferrin.

Milk contains a copper-binding glycoprotein, ceruloplasmin, also known as ferroxidase (EC 1.16.3.1) (see Wooten et al. 1996). Ceruloplasmin is an α_2-globulin with a MW of ~126,000 Da; it binds six atoms of copper per molecule and may play a role in delivering essential copper to the neonate.

β_2-Microglobulin

β_2-Microglobulin, initially called lactollin, was first isolated from acid-precipitated bovine casein by Groves et al. (1963). Lactollin, with a MW of 43,000 Da, is a tetramer of β_2-microglobulin, which consists of 98 amino acids, with a calculated MW of 11,636 Da. β_2-Microglobulin, a component of the immune system (see Groves and Greenberg 1982), is probably produced by proteolysis of a larger protein, mainly within the mammary gland; it has no known significance in milk.

Osteopontin

Osteopontin (OPN) is a highly phosphorylated acidic glycoprotein, consisting of 261 amino acid residues with a calculated MW of 29,283 (total MW of the glycoprotein, ~60,000 Da). OPN has 50 potential calcium-binding sites, about half of which are saturated under normal physiological concentrations of calcium and magnesium. OPN occurs in bone (it is one of the major non-collagenous proteins in bone), in many other normal and malignant tissues, in milk and urine and can bind to many cell types. It is believed to have a diverse range of functions (Denhardt and Guo 1993, Bayless et al. 1997), but its role in milk is not clear.

Proteose Peptone 3

Bovine proteose peptone 3 (PP3) is a heat-stable phosphoglycoprotein that was first identified in the proteose-peptone (heat-stable, acid-soluble) fraction of milk. Unlike the other peptides in this fraction, which are proteolytic products of the

caseins, PP3 is an indigenous milk protein, synthesised in the mammary gland. Bovine PP3 is a polypeptide of 135 amino acids, with five phosphorylation and three glycosylation sites. When isolated from milk, the PP3 fraction contains at least three components of MW $\sim$28, 18 and 11 kDa; the largest of these is PP3, while the smaller components are fragments thereof generated by plasmin (see Girardet and Linden 1996). PP3 is present mainly in acid whey but some is present in the MFGM also. Girardet and Linden (1996) proposed that its name should be changed to *lactophorin* or *lactoglycoporin*. PP3 has also been referred to as *the hydrophobic fraction of proteose peptone*.

Owing to its strong surfactant properties (Campagna et al. 1998), PP3 can prevent contact between milk lipase and its substrates, thus preventing spontaneous lipolysis. Although its amino acid composition suggests that PP3 is not a hydrophobic protein, it behaves hydrophobically, possibly owing to the formation of an amphiphilic α-helix, one side of which contains hydrophilic residues while the other side is hydrophobic. The biological role of PP3 is unknown.

Vitamin-Binding Proteins

Milk contains binding proteins for at least the following vitamins: retinol (vitamin A, i.e., β-Lg, see Section 'Molecular Properties of Milk Proteins'), biotin, folic acid and cobalamine (vitamin B_{12}). The precise role of these proteins is not clear but they may improve the absorption of vitamins from the intestine or act as antibacterial agents by rendering vitamins unavailable to bacteria. The concentration of these proteins varies during lactation, but the influence of other factors such as individuality, breed and nutritional status is not known. The activity of these proteins is reduced or destroyed on heating at temperatures somewhat higher than HTST pasteurisation.

Angiogenins

Angiogenins induce the growth of new blood vessels, that is angiogenesis. They have high sequence homology with members of the RNase A superfamily of proteins and have RNase activity. Angiogenesis is a complex biological process of which the ribonuclease activity of angiogenins is one of a number of essential biochemical steps that lead to the formation of new blood vessels (Strydom 1998).

Two angiogenins (ANG-1 and ANG-2) have been identified in bovine milk and blood serum. Both strongly promote the growth of new blood vessels in a chicken membrane assay. Bovine ANG-1 has 64% sequence identity with human angiogenin and 34% identity with bovine RNase A. The amino acid sequence of bovine ANG-2 has 57% identity with that of bovine ANG-1; ANG-2 has lower RNase activity than ANG-1. The function(s) of the angiogenins in milk is unknown; they may be part of a repair system to protect either the mammary gland or the intestine of the neonate and/or part of the host-defence system.

Kininogen

Two forms of kininogen have been identified in bovine milk, a high ($>$68 kDa) and a low (16–17 kDa) MW form (Wilson et al. 1989). Bradykinin, a biologically-active peptide containing nine amino acids that is released from the high MW kininogen by the action of the enzyme, kallikrein, has been detected in the mammary gland, and is secreted into milk, from which it has been isolated. Plasma kininogen is an inhibitor of thiol proteases and has an important role in blood coagulation. Bradykinin affects smooth muscle contraction, induces hypertension and is involved in natriuresis and diuresis. The biological significance of bradykinin and kininogen in milk is unknown.

Glycoproteins

Many of the minor proteins discussed previously are glycoproteins; in addition, several other minor glycoproteins have been found in milk and colostrum but their identity and function have not been elucidated fully. Some of these glycoproteins belong to a family of closely related, highly acidic glycoproteins, called M-1 glycoproteins. Some glycoproteins stimulate the growth of bifidobacteria, presumably *via* their amino sugars. One of the M-1 glycoproteins in colostrum, but which has not been detected in milk, is orosomucoid (α_1-acid glycoprotein), a member of the lipocalin family, which is thought to modulate the immune system.

One of the high MW glycoproteins in bovine milk is prosaposin, a neurotrophic factor that plays an important role in the development, repair and maintenance of the nervous system (Patton et al. 1997). It is a precursor of saposins A, B, C and D, which are sphingolipid-activator proteins, but saposins have not been detected in milk. The physiological role of prosaposin in milk is not known, although the potent biological activity of saposin C, released by digestion, could be important for the growth and development of the young.

Proteins in the Milk Fat Globule Membrane

About 1% of the total protein in milk is in the MFGM. Most of the proteins are present at trace levels, including many of the indigenous enzymes in milk. The principal proteins in the MFGM include MUC1 and MUC15, adipophilin, BTN and XDH (Keenan and Mather 2003, 2003, 2006). BTN is a very hydrophobic protein and has similarities to the Igs (for review see Mather 2000, 2011).

Growth Factors

A great diversity of protein growth factors (hormones), including epidermal growth factor, insulin, insulin-like growth factors 1 and 2, three human milk growth factors (α_1, α_2 and β), two mammary-derived growth factors (I and II), colony-stimulating factor, nerve growth factor, platelet-derived growth factor and bombasin, are present in milk. It is not clear whether these factors play a role in the development of the neonate or in the

development and functioning of the mammary gland, or both (Fox and Flynn 1992, Pihlanto-Leppala 2011, Wynn 2011).

Milk Protein-Derived Bioactive Peptides

The six lacto-proteins contain sequences, which when released on proteolysis display various biological activities (Pihlanto-Leppala 2011, Fosset and Tome 2011). Some of these peptides are formed in the GIT in vivo but it not known whether or not they are active in vivo.

Indigenous Milk Enzymes

Milk contains about 60 indigenous enzymes, which represent a minor but very important part of the milk protein system (for review, see Fox and Kelly 2006, Fox 2003b). The enzymes originate from the secretory cells or the blood. Many of the indigenous enzymes are concentrated in the MFGM and originate in the Golgi membranes of the cell or the cell cytoplasm, some of which occasionally becomes entrapped as crescents inside the encircling membrane during exocytosis. Plasmin and LPL are associated with the casein micelles and several enzymes are present in the milk serum, many of which are derived from the MFGM, which is shed during the storage of milk.

There has been interest in indigenous milk enzymes since lactoperoxidase was discovered in 1881. Although present at relatively low levels, the indigenous enzymes are significant for several reasons:

Nutritional and Protective   Some indigenous enzymes have a protective effect on the neonate or perhaps on the mammary gland of the mother, for example lysozyme, lactoperoxidase, superoxide dismutase and xanthine oxidoreductase. Many of the enzymes have the potential to participate in digestion but probably the only enzyme significant in this regard is bile salts stimulated lipase (carboxyl ester hydrolase, CEH) which is believed to make a significant contribution to lipolysis; human milk is particularly rich in CEH but it is also present in the milk of several other species.

Technological

- Plasmin causes proteolysis in milk and some dairy products; it may be responsible for age gelation in UHT milk and contributes to proteolysis in cheese during ripening, especially in varieties that are cooked at a high temperature, in which the coagulant is extensively or completely denatured, for example Emmental, Parmesan and Mozzarella.
- LPL may cause hydrolytic rancidity in milk and butter but contributes positively to cheese ripening, especially that made from raw milk.
- Acid phosphatase can dephosphorylate casein and modify its functional properties; it may contribute to cheese ripening.
- Xanthine oxidoreductase is a very potent pro-oxidant and may cause oxidative rancidity in milk; it reduces nitrate,

used to control the growth of clostridia in several cheese varieties, to nitrite.
- Lactoperoxidase is a very effective bacteriocidal agent in the presence of a low level of H_2O_2 and SCN^- and is exploited for the cold-sterilisation of milk.

Indices of Milk Quality and History

- The standard assay to assess the adequacy of HTST pasteurisation is the inactivation of alkaline phosphatase. Proposed assays for super-pasteurisation of milk are based on the inactivation of γ-glutamyltranspeptidase or lactoperoxidase.
- The concentration/activity of several enzymes in milk increases during mastitic infection and some have been used as indices of this condition, for example catalase, acid phosphatase and especially N-acetylglucosaminidase.

Antibacterial

- Milk contains several bactericidal agents, two of which are the enzymes, lysozyme and lactoperoxidase.

MILK SALTS

Milk contains six inorganic elements, Ca, Mg, Na, K, Cl and P, at substantial concentrations (macroelements) and about 20 more at trace levels (microelements). These elements are referred to as milk salts or, incorrectly, as minerals. In addition, milk contains citrate that interacts with and affects the state of inorganic salts. Although they are relatively minor constituents, the milk salts of milk have major effects on its technological and biological properties and there have been several reviews, including Holt (1997) and Lucey and Horne (2009).

When milk is heated in a muffle furnace at 500°C for approximately 5 hours, an ash derived mainly from the inorganic salts of milk and representing approximately 0.7%, w/w, of the milk, remains. However, the elements are changed from their original forms to oxides or carbonates and the ash contains P and S derived from caseins, lipids, sugar phosphates or high-energy phosphates. The organic salts, the most important of which is citrate, are oxidised and lost during ashing; some volatile metals, for example sodium, are partially lost. Thus, ash does not accurately represent the salts of milk. However, the principal inorganic and organic ions in milk can be determined directly by potentiometric, spectrophotometric or other methods. The typical concentrations of the principal elements, often referred to as macro-elements, are shown in Table 24.3. Considerable variability occurs, due, in part, to use of poor analytical methods and/or to samples from cows in very early or late lactation or suffering from mastitis. The micro-elements are very important from a nutritional viewpoint, some, for example Fe and Cu, are very potent lipid pro-oxidants and some, for example Fe, Mo, Zn, are enzyme co-factors.

Some of the salts in milk are fully soluble but others, especially calcium phosphate, exceed their solubility under the conditions in milk and occur partly in the colloidal state, associated with the

Table 24.3. Distribution of Organic and Inorganic Ions Between Soluble and Colloidal Phases of Bovine Milk

Species	Concentration (mg/L)	Soluble		Colloidal (%)
		%	Form	
Sodium	500	92	Ionised	8
Potassium	1450	92	Ionised	8
Chloride	1200	100	Ionised	–
Sulphate	100	100	Ionised	–
Phosphate	750	43	10% bound to Ca^{+2} and Mg^{+2}	57
			51% H_2PO4^-	
			39% HPO_4^{2-}	
Citrate	1750	94	84% bound to Ca and Mg	6
			14% $Citr^{3-}$	
			1% $HCitr^{2-}$	
Calcium	1200	34	35% Ca^{2+}	66
			55% bound to citrate	
			10% bound to phosphate	
Magnesium	130	67	Probably similar to calcium	33

Source: Modified from Fox and McSweeney 1998.

casein micelles; these salts are referred to as CCP, although some magnesium, citrate and traces of other elements are also present in the micelles. The typical distribution of the principal organic and inorganic ions between the soluble and colloidal phases is summarised in Table 24.3. The actual form of the principal species can be determined or calculated after making certain assumptions; typical values are shown in Table 24.3. Many of the micro-elements are bound by proteins, including enzymes, some of which are present in the MFGM.

The precise nature and structure of CCP are uncertain. It is associated with the caseins, probably *via* the casein phosphate residues; it probably exists as nanocrystals that include PO_4 residues of casein. The simplest stoichiometry is $Ca_3(PO_4)_2$ but spectroscopic data suggest that $CaHPO_4$ is the most likely form. CCP plays a major integrating role in the casein micelles, as discussed earlier.

The solubility and ionisation status of many of the principal ionic species are interrelated, especially H^+, Ca^{2+}, PO_4^{3-} and citrate^{3-}. These relationships have major effects on the stability of the caseinate system and consequently on the processing properties of milk. The status of various species in milk can be modified by adding certain salts to milk, for example [Ca^{2+}] by PO_4^{3-} or citrate^{3-}; addition of $CaCl_2$ to milk affects the distribution and ionisation status of calcium and phosphate and the pH of milk.

The distribution of species between the soluble and colloidal phases is strongly affected by pH and temperature. As the pH is reduced, CCP dissolves and is completely soluble < *ca*. pH 4.9; the reverse occurs when the pH is increased. These pH-dependent shifts mean that acid-precipitated products, for example acid casein and acid-coagulated cheeses, have a very low concentration of Ca.

The solubility of calcium phosphate decreases as the temperature is increased. Consequently, soluble calcium phosphate is transferred to the colloidal phase, with the release of H^+ and a decrease in pH:

$$CaHPO_4/Ca(H_2PO_4)_2 \leftrightarrow Ca_3(PO_4)_2 + 3H^+$$
These changes are quite substantial, but are at least partially reversible on cooling.

Since milk is supersaturated with calcium phosphate, concentration of milk by evaporation of water increases the degree of super-saturation and the transfer of soluble calcium phosphate to the colloidal state, with the concomitant release of H^+. Dilution has the opposite effect. The concentration of salts in milk may be modified by electrodialysis, ion exchangers or addition of chelators or selected salts; such operations are practised widely, for example for sterilised milks, processed cheese or nutritional products, such as infant formulae.

Milk salts equilibria are also shifted on freezing; as pure water freezes, the concentrations of solutes in unfrozen liquid are increased. Soluble calcium phosphate precipitates as $Ca_3(PO_4)_2$, releasing H^+ (the pH may decrease to 5.8). The crystallisation of lactose as a monohydrate aggravates the situation by reducing the amount of solvent water.

There are substantial changes in the concentrations of the macroelements in milk during lactation, especially at the beginning and end of lactation and during mastitic infection (see White and Davies 1958, Keogh et al. 1982, O'Keeffe 1984, O'Brien et al. 1999a). Changes in the concentration of some of the salts in milk, especially calcium phosphate and citrate, have major effects on the physico-chemical properties of the casein system and on the processability of milk, especially rennet coagulability and related properties and heat stability.

Table 24.4. Typical Concentrations of Vitamins in Milk and Proportion of Recommended Daily Allowance (RDA) Supplied by 1 L Milk

Vitamin	Average Level in 1 L Milk	RDA (%) in 1 L Milk
A	380 rational equivalents	38
B$_1$ (thiamine)	0.4 mg	33
B$_2$ (riboflavin)	1.8 mg	139
B$_3$ (niacin)	9.0 niacin equivalents	53
B$_5$ (pantothenic acid)	3.5 mg	70
B$_6$ (pyridoxine)	0.5 mg	39
B$_7$ (biotin)	30 g	100
B$_{11}$ (folic acid)	50 g	13
B$_{12}$ (cobalamin)	4 g	167
C	15 mg	25
D	0.5 g	10
E	1 mg	10
K	35 mg	44

VITAMINS

Milk contains all the vitamins in sufficient quantities to allow normal growth and maintenance of the neonate. Cow's milk is a very significant source of vitamins, especially biotin (B$_7$), riboflavin (B$_2$) and cobalamine (B$_{12}$), in the human diet. Typical concentrations of all the vitamins and the percentage of recommended daily allowance supplied by 1 L of milk are shown in Table 24.4. For specific aspects of vitamins in relation to milk and dairy products, including stability during processing and storage, the reader is referred to a set of articles in Roginski et al. (2002) or Fuquay et al. (2011).

In addition to their nutritional significance, four vitamins are of significance for other reasons, which have been discussed in Section 'Fat-Soluble Vitamins':

- Vitamin A (retinol), and especially carotenoids, are responsible for the yellow-orange colour of fat-containing products made from cows' milk.
- Vitamin E (tocopherols) is a potent antioxidant.
- Vitamin C (ascorbic acid) may act as an antioxidant or pro-oxidant, depending on its concentration.
- Vitamin B2 (riboflavin), which is greenish-yellow, is responsible for the colour of whey or UF permeate. It co-crystallises with lactose and is responsible for its yellowish colour, which may be removed by recrystallisation or bleached by oxidation. Riboflavin acts as a photocatalyst in the development of light-oxidised flavour in milk, which is due to the oxidation of methionine (not to the oxidation of lipids).

SUMMARY

Milk is a very complex fluid. It contains several hundred molecular species, mostly at trace levels. Most of the micro-constituents are derived from blood or mammary tissue but most of the macro-constituents are synthesised in the mammary gland and are milk-specific. The constituents of milk may be in true aqueous solution (e.g., lactose and most inorganic salts) or as a colloidal solution (proteins, which may be present as individual molecules or as large aggregates of several thousand molecules, called micelles) or as an emulsion (lipids). The macro-constituents can be fractionated readily and are used as food ingredients. The natural function of milk is to supply the neonate with its complete nutritional requirements for a period (sometimes, several months) after birth and with many physiologically important molecules, including carrier proteins, protective proteins and hormones.

The properties of milk lipids and proteins may be modified readily by biological, biochemical, chemical or physical means and thus converted into a wide range of dairy products. In this chapter, the chemical and physico-chemical properties of milk sugar (lactose), lipids, proteins and inorganic salts are discussed. The technology used to convert milk into a range of food products is described in Chapter 25.

Biochemistry of Milk Processing

A.L. Kelly and P.F. Fox

Abstract: Milk is subjected to a wide range of processes before consumption directly or in the form of the very wide range of modern dairy products. Primary objectives of processing involve rendering milk microbiologically safe or stable (e.g., pasteurisation, ultra-high temperature (UHT) milk), isolation of valuable components (e.g., whey proteins, caseins) and conversion to other forms (e.g., cheese, yoghurt, enzymatic hydrolysates). All such processes applied to milk have very significant effects on the properties and distribution of food constituents. The principal families of dairy products, which may be produced from milk, and their principles of production, are described in this chapter.

INTRODUCTION

As described in Chapter 24, milk is a very complex system; the continuous phase is an aqueous solution of a specific sugar, lactose, globular (whey/serum) proteins, inorganic salts and hundreds of minor constituents, for example vitamins, at trace levels. Dispersed in the aqueous phase as an oil-in-water (o/w) emulsion are lipids in the form of small globules and a second, unique group of proteins, the caseins, which exist as large colloidal

particles known as casein micelles, with an average diameter of approximately 150 nm (range 50–600 nm) and containing, on average, approximately 5000 protein molecules.

Owing to its physical state, milk is an unstable system. The fat globules, which are less dense than the aqueous phase, rise to the surface where they form a cream layer. The fat-rich cream can be skimmed off and used for the manufacture of butter, butter oil, ghee or other fat-rich products. Alternatively, the fat-depleted lower layer (skimmed milk) may be run off, for example through a valve at the bottom of a separating vat. The skimmed milk may be consumed directly as a beverage or used for the manufacture of a wide range of products. Gravity creaming and butter manufacture have been used since prehistoric times, but gravity creaming has been largely replaced by centrifugal separation of the fat since the development of the cream separator by Gustav de Laval in 1878. Gravity separation is still used to prepare reduced-fat milk for the manufacture of Parmigiano-Reggiano cheese. The physics of fat separation by gravity or centrifugal separation and the process of demulsifying milk fat to butter or butter oil will be described briefly later in this chapter.

Creaming (fat separation) is undesirable in many dairy products (e.g., liquid/beverage milk, concentrated milks) and is prevented by a process known as homogenisation (the commonly used valve homogeniser was developed by Auguste Gaulin in 1899). Homogenisation prevents creaming by reducing the size of the fat globules and preventing their agglomeration (cluster-ing), by denaturing a particular minor protein known as cryo-globulin (type M immunoglobulin).

The casein micelles are physicochemically stable but can be destabilised by a number of processes/treatments, which are exploited for the production of new dairy products. The most important of these are limited proteolysis and acidification, which are used in the production of cheese, fermented milks and functional milk proteins. The mechanism and consequences of proteolysis and acidification will be described briefly. Thus, the three main constituents/phases of milk, that is fat, casein and the aqueous solution (whey), can be separated easily.

Milk is remarkably heat stable; it can be sterilised by heat in standard or concentrated form, or dried to produce a wide range of dairy products. The principal processes and the resulting product families are summarised in Table 25.1. All these families of dairy products contain many products, for example approximately 1400 varieties of cheese are produced worldwide.

In addition to the above considerations, milk is a rich medium for the growth of a wide range of microorganisms. While this is exploited in the production of a range of fermented dairy products, it also means that milk can harbour microorganisms that may cause spoilage of products, or present health risks to the consumer. Largely for the latter reason, very little raw milk is now consumed, the vast majority being heat treated sufficiently severe to kill all pathogenic and food-poisoning bacteria.

Table 25.1. Diversity of Dairy Products Produced by Different Processes

Process	Primary (*italic*) and Secondary Products
Heat treatment (generally with homogenisation)	*Market milk*
Centrifugal separation	*Standardised milk*
	Cream
	Butter, butter oil, ghee
	Creams of various fat content (pasteurised or UHT treated); whipping, coffee, dessert creams
	Skim milk
	Skim milk powder, casein, cheese, protein concentrates
Concentration (e.g., evaporation or membrane separation)	In-container or UHT-sterilised concentrated milks, sweetened condensed milk
Concentration and drying	Whole milk powders, infant formulae
Enzymatic coagulation	*Cheese*
	Numerous varieties, processed cheese, cheese sauces and dips
	Rennet casein; cheese analogues
	Whey
	Whey powders; demineralised whey powders; whey protein concentrates; fractionated whey proteins; whey protein hydrolysates; lactose and lactose derivatives
Acid coagulation	*Cheese (fresh)*
	Acid casein; functional proteins
	Whey (as rennet whey)
Fermentation	*Various fermented milk products*, e.g., yoghurt, buttermilk, acidophilus milk, bioyoghurt
Freezing, aeration and whipping	*Ice cream*

Source: Adapted From Fox and McSweeney 1998.
UHT, ultra-high temperature.

In this chapter, several of the main processes used in the modern dairy industry will be discussed and the relationships between the biochemical properties of milk and the processes applied, explored.

THERMAL PROCESSING OF MILK

INTRODUCTION

The most common process applied to most food products is probably heat treatment, principally used to kill microorganisms (e.g., bacteria, yeasts, moulds and viruses) responsible for foodborne disease, food poisoning or spoilage. Secondary objectives of heat-treating foods include inactivation of enzymes in the tissue or fluid, which would otherwise negatively influence product quality, and effecting changes in the structure of the food, for example through denaturation of proteins or gelatinisation of starch.

Today, a wide range of thermal processes are commonly applied to milk, as summarised in Table 25.2.

The most widely used thermal process for milk is pasteurisation. In 1864–1866, Louis Pasteur, the famous French scientist, discovered that the spoilage of wine and beer could be prevented by heating the product to around 60°C for several minutes; this process is now referred to as pasteurisation. The historical development of the thermal processing of milk was reviewed by Westhoff (1978).

Although pasteurisation was introduced to improve the stability and quality of food, it soon became apparent that it offered consumers protection against hazards associated with the consumption of raw milk (particularly the risk of transmission of tuberculosis from infected cows to humans); developments in technology and widespread implementation occurred early in the nineteenth century. The first commercial pasteurisers, in which milk was heated at 74°C–77°C for an unspecified time period, were made by Albert Fesca in Germany in 1882 (Westhoff 1978). The first commercially operated milk pasteuriser in the United States was installed in Bloomville, New York, in 1893; the first law requiring the pasteurisation of liquid (beverage) milk was passed by the authorities in Chicago in 1908.

Many early pasteurisation processes used conditions not very different from those proposed by Pasteur, generally heating milk to 62–65°C for at least 30 minutes, followed by rapid cooling to less than 10°C (now referred to as low-temperature long-time, LTLT, pasteurisation). However, high-temperature short-time (HTST) pasteurisation, in which milk is treated at 72–74°C for 15 seconds in a continuous-flow plate heat exchanger, was introduced by APV in 1923 and gradually became the standard industrial procedure for the heat treatment of liquid milk and cream. Compared to the LTLT process, the HTST process has the advantages of reduced heat damage and flavour changes, reduced cost and increased efficiency and throughput (Kelly and O'Shea 2002).

Later developments in the thermal processing of milk led to the development of ultra-high temperature (UHT) processes, in which milk is heated to a temperature in the range 135–140°C for 2–5 seconds (Lewis and Heppell 2000). UHT treatments can be applied using a range of heat exchanger technologies (e.g., indirect and direct processes), and essentially result in a sterile product that is typically shelf-stable for at least 6 months at room temperature; eventual deterioration of product quality generally results from physicochemical rather than microbiological or enzymatic processes.

Sterilised milk products may also be produced using in-container retort systems; in fact, such processes were developed before the work of Pasteur. In 1809, Nicholas Appert developed an in-container sterilisation process that he applied to the preservation of a range of food products, with varying degrees of success. Today, in-container sterilisation, as first successfully and consistently applied towards the end of the nineteenth century, is generally used for concentrated (condensed) milks; typical conditions involve heating at 115°C for 10–15 minutes. A related, although not sterile, class of product is preserved by adding a high level of sugar to concentrated milk; the sugar preserves the product through osmotic action (sweetened condensed milk was patented by Gail Borden in 1856).

The primary function of thermal processing of milk is to kill undesirable microorganisms; modern pasteurisation is a very

Table 25.2. Thermal Processes Commonly Applied to Liquid Milk Products

Process	Conditions	Heat Exchanger	Reason
Thermisation	63°C for 15 s	Plate heat exchanger	Killing psychrotrophic bacteria before cold storage of milk
Pasteurisation	72–74°C for 15–30 s	Plate heat exchanger	Killing of vegetative pathogenic bacteria and shelf-life extension
UHT (indirect)	135–140°C for 3–5 s	Plate heat exchanger Scraped-surface heat exchanger Tubular heat exchanger	Production of safe long shelf-life milk
UHT (direct)	135–140°C for 3–5 s	Steam infusion system Steam injection system	Production of safe long shelf-life milk
Sterilisation	118°C for 12 min	Batch or continuous Retort	Production of sterile Long-life milk

UHT, ultra-high temperature.

effective means for ensuring that liquid milk is free of the most heat-resistant pathogenic bacteria likely to be present in raw milk. The original target species was *Mycobacterium tuberculosis* but, a little later, *Coxiella burnetti* became the target. In recent years, evidence for the survival of *Listeria monocytogenes* and, in particular, *Mycobacterium avium* subsp. *paratuberculosis* in pasteurised milk is of concern and the subject of ongoing research (Grant et al. 2001, Ryser 2002). Most health risks linked to the consumption of pasteurised milk are probably due to post-pasteurisation contamination of the product.

HEAT-INDUCED CHANGES IN MILK PROTEINS

The caseins are very resistant to temperatures normally used for processing milk and, in general, unconcentrated milk is stable to the thermal processes to which it is exposed, for example HTST pasteurisation, UHT or in-container sterilisation. However, very severe heating (e.g., at 140°C for a prolonged period) causes simultaneous dissociation and aggregation of the micelles and eventually coagulation.

However, the whey proteins are typical globular proteins and are relatively susceptible to changes on heating milk. β-Lactoglobulin (β-lg) is susceptible to thermal denaturation, to an extent dependant on factors such as pH, protein concentration and ionic strength (Sawyer 2003); denaturation exposes a highly reactive sulphydryl (-SH) group. Denatured β-lg can react, *via* sulphydryl–disulphide interchange reactions, with other proteins including κ-casein, the micelle-stabilising protein that is concentrated at the surface of the casein micelles. Thus, heating milk at a temperature higher than that used for minimal HTST pasteurisation (which itself causes only low levels of denaturation of β-lg, although even slightly higher temperatures will cause progressively increased levels of denaturation) results in the formation of casein/whey protein complexes in milk, with major effects on many technologically important properties of milk.

Such complexes are found either at the surface of the micelles or in the serum phase, depending on the pH, which determines the likelihood of heat-induced dissociation of the κ-casein/β-lg complex from the casein micelles. Largely as a result of this, the heat stability of milk (expressed as the number of minutes at a particular temperature, for example 140°C, before visible coagulation of the milk occurs – the heat coagulation time, HCT) is highly dependent on pH, with large differences over a narrow range of pH values (O'Connell and Fox 2003).

Most milk samples show a type A heat stability–pH profile, with a pronounced minimum and maximum, typically around pH 6.7 and 7.0, respectively, with decreasing stability on the acidic side of the maximum and increasing stability on the alkaline side of the minimum. The rare type B HCT–pH profile has no minimum, and heat stability increases progressively throughout the pH range 6.4–7.4.

In addition to pH, a number of factors affect the heat stability of milk (O'Connell and Fox 2002), including:

- Reduction in the concentration of Ca^{2+} or Mg^{2+} increases stability in pH range 6.5–7.5

- Lactose hydrolysis increases heat stability throughout the pH range
- Addition of κ-casein eliminates the minimum in the type A profile
- Addition of β-lg to a type B milk converts it to a type A profile
- Addition of phosphates increases heat stability
- Reducing agents reduce heat stability and convert a type A to a type B profile
- Alcohols and sulphydryl-blocking agents reduce the heat stability of milk

Concentrated (e.g., evaporated) milk is much less thermally stable than unconcentrated milk and its HCT–pH profile, normally assayed at 120°C, is quite different (O'Connell and Fox 2003). It shows a maximum at approximately pH 6.4, with decreasing stability at higher and lower pH values (Fig. 25.1).

Severe heating has a number of effects on the casein molecules, including dephosphorylation, deamidation of glutamine and asparagine residues, cleavage and formation of covalent cross-links; these changes may result in protein–protein interactions that contribute to thermal instability.

The heat stability of milk of different species differ, primarily due to differences in protein and mineral content; for example equine, camel, buffalo and caprine milk are less heat stable than bovine milk (O'Connell and Fox 2003).

STABILITY OF UHT MILK ON STORAGE

UHT milk is stable to long-term storage at ambient temperatures if microbiological sterility has been achieved by the thermal process and maintained by aseptic packaging in hermetically sealed containers. The shelf life of UHT milk is often limited by
Figure 25.1. Heat coagulation time (HCT)–pH profiles of typical type A bovine milk (____), type B or serum protein-free milk (_ _ _ _), as determined at 140°C, or concentrated milk (......), as determined at 120°C.

age gelation, which refers to a progressive increase in viscosity during storage, followed by the formation of a gel that cannot be redispersed. The mechanism of age gelation is not completely understood, but is probably due to one or both of the following:

1. *Physicochemical factors:* For example dissociation of casein/whey protein complexes; changes in casein micelle structure and/or properties; cross-linking due to the Maillard reaction; removal or binding of Ca^{2+}.
2. *Biochemical factors:* For example action of proteolytic enzymes, such as plasmin or heat-stable bacterial proteinases (i.e., from *Pseudomonas* species), which may hydrolyse κ-casein, inducing micelle coagulation.

Recent reviews on this subject include Nieuwenhuijse (1995), Datta and Deeth (2001) and Nieuwenhuijse and van Boekel (2003).

HEAT-INDUCED CHANGES IN LACTOSE IN MILK AND THE MAILLARD REACTION

Heating lactose causes several chemical modifications, the nature and extent of which depend on environmental conditions and the severity of heating; changes include degradation to acids (with a concomitant decrease in pH), isomerisation (e.g., to lactulose), production of compounds such as furfural and interactions with amino groups of proteins (Maillard reaction).

In the Maillard reaction, lactose or lactulose reacts with an amino group, such as the ε-amino group of lysine residues, in a complex (and not yet fully understood) series of reactions with a variety of end products (O'Brien 1995, van Boekel and Walstra 1998; O'Brien 2009). The early stages of the Maillard reaction result in the formation of a protein-bound Amadori product, lactulosyllysine, which then degrades to a range of advanced Maillard products, including hydroxymethylfurfural, furfurals and formic acid. The breakdown of lactose to organic acids reduces the pH of milk. The most obvious result of the Maillard reaction is a change in the colour of milk (browning), due to the formation of pigments called melanoidins, or advanced-stage Maillard products; extensive Maillard reactions also result in the polymerisation of proteins. The Maillard reaction also changes the flavour and nutritive quality of dairy products, in the latter case through reduced digestibility of the caseins and loss of available lysine.

Moderately intense heating also causes the isomerisation of lactose to lactulose. Lactulose, a disaccharide of galactose and fructose that does not occur naturally, is of interest as a bifidogenic factor and as a laxative. More severe treatments (e.g., sterilisation) will result preferentially in Maillard reactions.

There is particular interest in the use of products of heat-induced changes in lactose, such as lactulose and forosine, as indices of heat treatment of milk (Birlouez-Aragon et al. 2002).

HEAT-INDUCED CHANGES IN MILK LIPIDS

There are little effects of heating on milk triglycerides at the temperatures commonly encountered in dairy processing. Heating at modest temperatures can promote oxidation of lipids, but more severe heating inhibits oxidation (van Boekel and Walstra 1998). However, heat-induced denaturation of whey proteins can result in their interaction with the milk fat globule membrane (MFGM) (Huppertz et al. 2009). Because of denaturation of immunoglobulins, creaming due to cold agglutination of milk fat globules is prevented in heated milk.

INACTIVATION OF ENZYMES ON HEATING OF MILK

Heat treatment of milk inactivates many enzymes, both indigenous and endogenous (i.e., of bovine or bacterial origin). The inactivation of enzymes is of interest, both for the stability of heated milk products and as indices of heat treatment. Thermal inactivation characteristics of a number of indigenous milk enzymes are summarised in Table 25.3.

Because of its importance, the thermal inactivation kinetics of several milk enzymes have been studied in detail (Andrews et al. 1987). A case of particular interest is that of alkaline phosphatase, which has been used since 1925 as an indicator of the adequacy of pasteurisation of milk, because its thermal inactivation kinetics in milk closely approximate those of

Table 25.3. Thermal Inactivation Characteristics of Some Indigenous Milk Enzymes

Enzyme	Characteristics
Alkaline phosphatase	Inactivated by pasteurisation; index of pasteurisation; may reactivate on storage
Lipoprotein lipase	Almost completely inactivated by pasteurisation
Xanthine oxidase	May be largely inactivated by pasteurisation, depending on whether milk is homogenised or not
Lactoperoxidase	Affected little by pasteurisation; inactivated rapidly around 80°C; used as an index of flash pasteurisation or pasteurisation of cream
Sulphydryl oxidase	About ∼40% of activity survives pasteurisation, completely inactivated by UHT
Superoxide dismutase	Largely unaffected by pasteurisation
Catalase	Largely inactivated by pasteurisation but may reactivate during subsequent cold storage
Acid phosphatase	Very thermostable; survives pasteurisation
Cathepsin D	Largely inactivated by pasteurisation
Amylases (α and β)	Largely inactivated; β more stable than α
Lysozyme	Largely survives pasteurisation

M. tuberculosis. A negative result (residual activity below a set maximum value) in a phosphatase test (assay) is regarded as an indication that milk has been pasteurised correctly (Wilbey 1996). Detailed kinetic studies on the thermal inactivation of alkaline phosphatase under conditions similar to pasteurisation have been published (McKellar et al. 1994, Lu et al. 2001).

To test for over-pasteurisation (excessive heating) of milk, a more heat-stable enzyme, for example lactoperoxidase, has been used as the indicator enzyme (Storch test); lactoperoxidase may also be used as an index of the efficacy of pasteurisation of cream, which must be heated more severely than milk to ensure the killing of target bacteria, due to the protective effect of the fat therein.

Recently, other enzymes have been studied as indicators (sometimes called Time Temperature Integrators, TTIs) of heat treatments (particularly at temperatures above 72°C) that may be applied to milk; these include catalase, lipoprotein lipase, acid phosphatase, *N*-acetyl-β-glucosaminidase and γ-glutamyl-transferase (McKellar et al. 1996, Wilbey 1996). The latter has been a focus of particular attention due to its potential role as an indicator of the efficacy of heat treatments in the range 70–80°C for 16 seconds (McKellar et al. 1996).

The alkaline milk proteinase, plasmin, is resistant to pasteurisation; indeed, its activity may increase during storage of pasteurised milk, due to inactivation of inhibitors of plasminogen activators (Richardson 1983). Treatment under UHT conditions greatly reduces plasmin activity (Enright et al. 1999); there is some evidence that the low level of plasmin activity in UHT milk contributes to the destabilisation of the proteins, leading to defects such as age gelation, although this is not universally accepted (for review see Datta and Deeth 2001).

Since most indigenous milk enzymes are inactivated in UHT-sterilised milk products and in all in-container sterilised products, enzymes are not suitable indices of adequate processing and chemical indices are more usually used (e.g., the concentration of lactulose or extent of denaturation of β-lg). The use of a range of indicators for different heat treatments applied to milk was reviewed by Claeys et al. (2002).

The thermal inactivation of bacterial enzymes in milk is also of considerable significance. For example, psychrotrophic bacteria of the genus *Pseudomonas* produce heat-stable lipases and proteases during growth in refrigerated milk; while pasteurisation readily kills the bacteria, the enzymes survive such treatment and may contribute to the deterioration of dairy products made therefrom (Stepaniak and Sørhaug 1995). *Pseudomonas* enzymes partially survive in UHT milk and may be involved in its age gelation (Datta and Deeth 2001).

CHANGES ON EVAPORATION AND DRYING OF MILK

Dehydration, either partial (e.g., concentration to ~40–50% total solids, TS) or (almost) total (e.g., spray-drying to ~96–97% TS) is a common method for the preservation of milk. Reviews of the technology of drying of milk and its effects on milk quality include Caríc and Kalab (1987), Pisecký (1997), Early (1998) and Kelly et al. (2003).

CONCENTRATION OF MILK

The most common technology for concentrating milk is thermal evaporation in a multi-effect (stage) falling-film evaporator, which is used either as a prelude to spray-drying, to increase the efficiency of the latter, or to produce a range of concentrated dairy products (e.g., sterilised concentrated milk, sweetened condensed milk).

In many processes, a key stage in milk evaporation is preheating the feed. The minimum requirements of this step are to pasteurise the milk (e.g., skim milk, whole milk, filled milk) to ensure food safety and to bring its temperature to the boiling point in the first effect of the evaporator, for thermal efficiency. However, the functionality of the final product can be determined and modified by this processing step; preheating conditions range from conventional pasteurisation to 90°C for 10 minutes or 120°C for 2 minutes. The most significant result of such heating is denaturation of β-lg, to a degree depending on the severity of heating. During subsequent evaporation and, if applied, spray-drying, relatively little denaturation of the whey proteins occurs, as the temperature of the milk generally does not exceed 70°C (Singh and Creamer 1991). However, further association of whey proteins with the casein micelles can occur during evaporation, probably because the decrease in pH reduces protein charge, facilitating association reactions (Oldfield 1998).

Evaporation also increases the concentrations of lactose and salts in milk and induces a partially reversible transfer of soluble calcium phosphate to the colloidal form, with a concomitant decrease in pH (Le Graet and Brule 1982, Nieuwenhuijse et al. 1988, Oldfield 1998). The extent of the transfer of phosphate to the colloidal phase, which is greater than that of calcium, depends on the temperature of preheating. The concentrations of soluble calcium and phosphate in reconstituted milk powder are generally lower than those in the original milk, due to irreversible shifts induced during drying (Le Graet and Brule 1982).

Holding milk concentrate at >60°C for an extended period before spray-drying can increase the viscosity of the concentrate, making it more difficult to atomise and thereby affecting the properties of the final powder.

Alternative technologies for concentrating milk are available, the most significant of which is probably membrane separation using reverse osmosis (RO). RO can achieve only a relatively low level of total solids (<20%) and has a relatively low throughput, but is far less thermally severe than evaporation (Pisecký 1997). Other membrane techniques may be used to concentrate or fractionate milk, such as nanofiltration (NF), which essentially removes only water, and ultrafiltration (UF), which allows standardisation of the composition (e.g., protein and lactose contents) of the final powder (Mistry and Pulgar 1996, Horton 1997). The most significant area of application for membrane processing in the dairy industry to date is probably in whey processing, as will be discussed below.

SPRAY-DRYING OF MILK

Today, milk powders are produced in large, highly efficient spray-dryers; the choice of dryer design (e.g., single versus

multi-stage, with integrated or external fluidised bed drying steps, choice of atomiser, air inlet and outlet temperatures) depends on the final product characteristics required. Because of a wide range of applications of milk powders, from simple reconstitution to use in cheese manufacture or incorporation as an ingredient into complex food products, the precise functionality required for a powder can vary widely.

Skim milk powders (SMP) are usually classified on the basis of heat treatment (mostly meaning the intensity of preheating during manufacture), which influences their flavour and solubility (Caríc and Kalab 1987, Kyle 1993, Pellegrino et al. 1995). Instant powders (readily dispersible in cold or warm water) are desirable for applications requiring reconstitution in the home, and are produced by careful production of agglomerated powders containing an extensive network of air spaces that can fill rapidly with water on contact (Pisecký 1997). A number of techniques are used to produce agglomerated powders, including feeding fines (small powder particles) back to the atomisation zone during drying (in straight-through agglomeration processes) or wetting dry powder in chambers that promote aggregation of moistened particles that, when subsequently dried, produce porous agglomerated powder particles (rewet processes).

Milk powder contains occluded air (i.e., contained in vacuoles within individual powder particles) and interstitial air (i.e., entrapped between neighbouring powder particles). The amount of occluded air depends on the heat treatment applied to the feed (whey protein denaturation affects foaming properties), method of atomisation and outlet air temperature, while the interstitial air content of a powder depends on the size, shape and surface geometry of individual powder particles. The drying process can be manipulated (e.g., by using multiple stages or by returning fines to the atomisation zone) to increase the levels of interstitial and occluded air and instantise the powder (Kelly et al. 2003).

In the case of whole milk powders (WMP), a key characteristic is the state of the milk fat, whether fully emulsified or partially in free form (the latter is desirable for WMP used in chocolate manufacture). The production of instant WMP requires the use of an amphiphilic additive such as lecithin, as well as agglomeration, to overcome the intrinsic hydrophobicity of milk fat (Jensen 1975, Kim et al. 2009). Lecithin may be added either during multi-stage drying of milk (between the main drying chamber and the fluidised bed dryer) or separately in a rewet process.

During spray-drying of milk, there is relatively little change in milk proteins, apart from that caused by preheating and evaporation. The constituent most affected by the drying stage *per se* is probably lactose that, on the rapid removal of moisture from the matrix, assumes an amorphous glassy state, which is hygroscopic and can readily absorb moisture if the powder is exposed to a high relative humidity. This can result in the crystallisation of lactose, with a concomitant uptake of water, which can cause caking and plasticisation of the powder (Kelly et al. 2003).

Amorphous lactose is the principal constituent of both SMP and WMP and forms the continuous matrix in which proteins, fat globules and air vacuoles are dispersed. In products containing a very high level of lactose (e.g., whey powders, SMP), the lactose may be pre-crystallised to avoid the formation of an amorphous glass. Usually, small lactose crystals are added to milk or whey concentrate prior to drying to promote crystallisation under relatively mild conditions (i.e., in the liquid rather than the powder form); the added crystals act as nuclei for crystallisation.

FREEZING OF MILK

When milk is cooled to temperatures below approximately –0.54°C, pure ice crystals form, and the remainder of the milk, thus, becomes progressively more concentrated at lower temperatures. This results in changes in milk that are analogous to those occurring on concentration by other means, including decrease in pH and increase in Ca^{2+} activity. At temperatures below approximately –23°C, the non-frozen portion of milk is in a glassy state, and changes cease, due to diffusion coefficients being close to zero. On thawing of frozen milk, aggregation of casein micelles due to salting out may occur, as may clumping of fat globules, due to mechanical damage to globule membranes by ice crystals.

CHEESE AND FERMENTED MILKS

INTRODUCTION

About 35% of total world milk production is used to produce cheese ($\sim 16 \times 10^6$ tonnes per annum), mainly in Europe, North and South America, Australia and New Zealand. Cheese manufacture essentially involves coagulating the casein micelles to form a gel that entraps the fat globules, if present; when the gel is cut or broken the casein network contracts (synereses), expelling whey. The resulting curds may be consumed fresh as mild-flavoured products, or ripened for a period ranging from 2 weeks, for example for Mozzarella, to >2 years, for example for Parmigiano-Reggiano.

Cheese is undoubtedly the most biochemically complex dairy product. However, since the action of rennet on milk and dairy fermentations are described in Chapters 33 and 27, respectively, only a brief summary is given here. For more detailed discussion of the science and technology of cheesemaking, see also Robinson and Wilbey (1998), Law (1999), Eck and Gillis (2000) and Fox et al. (2004), McSweeney (2007) and a number of articles in the Encyclopedia of Dairy Science (2011).

The coagulation of milk for cheese is achieved by one of three methods:

1. Rennet-induced coagulation, which is used for most ripened cheeses, and accounts for approximately 75% of total cheese production,
2. Acidification to pH approximately 4.6 at 30–36°C by *in situ* production of acid by fermentation of lactose to lactic acid by lactic acid bacteria (LAB; *Lactococcus*, *Lactobacillus* or *Streptococcus*) or direct acidification with acid or acidogen (e.g., gluconic acid-δ-lactone). Most acid-coagulated cheeses are consumed fresh and represent approximately 25% of total cheese production. Major examples of acid-coagulated cheeses are Cottage, Quarg and Cream cheeses,

3. Acidification of milk, whey or mixtures thereof to pH approximately 5.2 and heating to approximately 90°C. These cheeses are usually consumed fresh; common examples include Ricotta and variants thereof, Manouri and some forms of Queso Blanco.

RENNET-COAGULATED CHEESES

These cheeses, which represent approximately 75% of total production, are produced in a great diversity of shapes, flavours and textures (~1400 varieties worldwide). Their production can be divided into two phases: (1) conversion of milk to cheese curd and (2) ripening of the curd (Fig. 25.2B).

Cheese may be made from milk of many species, with bovine, ovine and caprine being most common globally. Cheese may be made from raw or pasteurised milk, and in large-scale industrial cheese production the latter is far more common, with some exceptions. The heat treatment applied is normally conventional HTST pasteurisation, as more severe treatments may impair the coagulation properties of milk due to heat-induced interaction of whey proteins and casein micelles. Other pre-treatments that may be applied to cheese milk include adjustment of the fat:protein or fat:casein ratio (i.e., standardisation) to achieve certain targets for cheese composition, and addition of $CaCl_2$,

Figure 25.2. Principles of manufacture of (**A**) acid-coagulated and (**B**) rennet-coagulated cheese.

which may be used to adjust for seasonal differences in mineral balance of milk. For some varieties, milk pH may be reduced (e.g., by adding gluconic acid-δ-lactone) prior to coagulation.

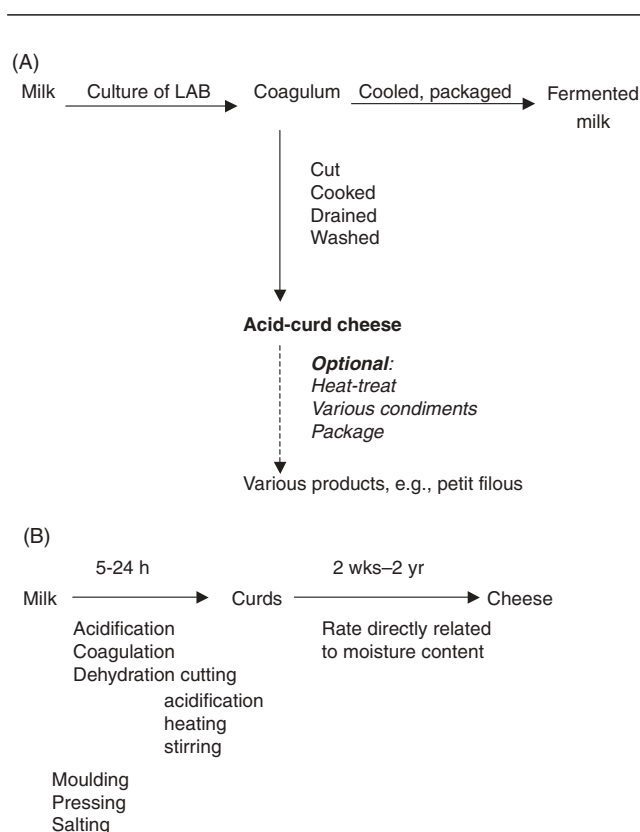
Coagulation

The coagulation of milk for the production of rennet-coagulated cheese exploits a unique characteristic of the casein system. As described in Chapter 24, the casein in milk exists as large (diameter 50–600 nm, mean 150 nm) colloidal particles, known as casein micelles. The micelles are stabilised by κ-casein, which is concentrated on the surface, with its hydrophobic N-terminal segment interacting with the α_{s1}−, α_{s2}− and β-caseins, and its hydrophilic C-terminal third protruding into the aqueous environment, forming a layer approximately 7 nm thick, which stabilises the micelles by a zeta potential of about –20 mV and by steric stabilisation. The stability of the micelles is lost when the surface κ-casein layer is destroyed by heat, alcohol or proteinases (known as rennets).

Several proteinases can coagulate milk but the traditional and the most effective rennets are NaCl extracts of the stomachs of young, milk-fed calves, kids or lambs. The active enzyme in these rennets is chymosin; as the animal ages, the secretion of chymosin decreases and is replaced by pepsin. The supply of chymosin has been inadequate for about 50 years due to the increased production of cheese and reduced availability of calf stomachs (due to the birth of fewer calves and the slaughter of calves at an older age). This shortage has led to a search for alternative coagulants (rennet substitutes).

Many, perhaps most, proteinases can coagulate milk under certain conditions, but almost all are unsuitable as rennets because they are too proteolytic, resulting in a reduced yield of cheese curd and off-flavoured cheese. Only five successful rennet substitutes have been identified: (1) bovine and (2) porcine pepsins and acid proteinases from (3) *Rhizomucor mehei,* (4) *Rhizomucor pusillus* and (5) *Cryphonectria parasitica*. Plant rennets (e.g., that from *Cynara cardunculus*) have also been studied as possible coagulants, but have high proteolytic activity relative to their milk-clotting activity, which may lead to bitterness in cheese. Plant rennets have been most successfully used for cheese varieties made in Spain and Portugal from ovine milk (e.g., Torta del Casar and Serra Da Estrela), in which bitterness does not seem to be a problem.

Rennet pastes, including those from kids or lambs, have been traditionally used for some hard Italian and Greek cheese varieties. These are less purified than conventional calf rennet, and include a lipase, pregastric esterase (PGE), which contributes to lipolysis during ripening of these varieties. The calf chymosin gene has been cloned in *Kluyveromyces lactis, Escherichia coli* and *Aspergillus niger* and fermentation-produced chymosin is now used widely.

Chymosin and most of the other commercially successful rennets hydrolyse κ-casein specifically at the Phe_{105}−Met_{106} bond; *C. parasitica* proteinase cleaves κ-casein at Ser_{104}−Phe_{105}. The liberated hydrophilic C-terminal segment, known as the (glyco) caseinomacropeptide (CMP), diffuses into the surrounding aqueous phase and the stability of the micelles is destroyed.


When approximately 85% of the κ-casein has been hydrolysed, the rennet-altered micelles aggregate to form a gel in the presence of a critical concentration of Ca^{2+} and at a temperature about >18°C.

Acidification

The second characteristic step in cheesemaking is acidification of the milk and curd from pH approximately 6.7 to a value in the range 4.6–5.2, depending on the variety. Until relatively recently, and for some minor artisanal varieties still, acidification was due to the production of lactic acid from lactose by adventitious LAB. Today, cheese milk is inoculated with a culture (starter) of selected LAB for more controlled and reproducible acidification. If the cheese curds are cooked to <40°C, a culture of *Lactococcus lactis* and/or *cremoris* is used, but for high-cooked cheese (curds cooked to 50–55°C), a culture of *Lactobacillus delbrueckii* subsp. *bulgaricus,* possibly in combination with *Streptococcus thermophilus,* is used. Cheese starters have been refined progressively over the years, especially with respect to the rate of acidification, resistance to bacteriophage and cheese-ripening characteristics. Today, mixtures of highly selected defined strains of LAB are used widely.

Acidification at the correct rate and time is essential for successful cheesemaking; it affects at least the following aspects:

- Activity and stability of the coagulant during renneting
- Strength of the rennet-induced gel
- Rate and extent of syneresis of the gel when cut and hence the composition of the cheese
- Retention of rennet in the curd
- Dissolution of colloidal calcium phosphate; the concentration of calcium in the cheese has a major effect on the texture and functionality of cheese
- Inhibition of growth of undesirable microorganisms, especially pathogenic bacteria
- Activity of various enzymes in the cheese during ripening

Post-Coagulation Operations

If left undisturbed, a rennet-coagulated milk gel is quite stable, but if cut or broken, it synereses (contracts), producing curds and whey. By controlling the rate and extent of syneresis, the cheese maker controls the moisture content of cheese and thereby, the rate and pattern of ripening and the quality and stability of the cheese.

Traditionally, the point at which the gel was ready to be cut was judged by the cheese maker based on experience; however, in some modern cheesemaking systems, this decision may be made automatically based on sensors in the vat or rheological measurements (Fagan et al. 2008).

Syneresis is affected by:

- Concentrations of fat, protein and calcium
- Denaturation of whey protein
- pH
- Size of curd particles
- Temperature of cooking

- Stirring the curds–whey mixture and the curds after whey drainage
- Pressing of the curd
- Salting (2 kg H_2O lost per kg NaCl taken up; NaCl should not be used to control moisture content)

When the desired degree of syneresis has occurred, as judged subjectively by the cheese maker, the curds and whey are separated, usually on some form of perforated metal screen. The curds are subjected to various treatments that are more or less variety-specific. These include cheddaring, kneading–stretching, moulding, pressing and salting. Salt is added to essentially all cheese varieties, but may be added either in dry form (e.g., for Cheddar cheese) or, more commonly, through immersion of the cheese in brine for sufficient time for salt uptake to the desired final level, followed by enough time for diffusion throughout the cheese so as to achieve a uniform concentration. The functions of salt in cheese are in flavour and control of bacterial growth and metabolism.

The extent of physical force applied to cheese curd during the later stages of manufacture depends on the target final moisture content, and may range from significant pressures being applied through piling of curds in the vat followed by pressing in moulds (Cheddar), to very light drainage under gravity in perforated moulds (e.g., Camembert). In addition, variety-specific techniques such as heating–stretching may be used at the final stages to achieve specific desirable functional properties (e.g., for Mozzarella).

Ripening

Rennet-coagulated cheese curd may be consumed at the end of the manufacturing process, and a little is, for example Junket or Burgos cheese, but most is ripened (matured) for a period ranging from approximately 2 weeks (Mozzarella) to >2 years (Parmigiano-Reggiano, extra-mature Cheddar) during which the characteristic flavour, texture and functionality of the cheese develop. The principal changes in cheese during ripening are listed in Table 25.4.

Ripening is a very complex biochemical process, catalysed by:

- *Coagulant*: Depending on the coagulant used, the pH of the curd at whey drainage, the temperature to which the curds are cooked and the moisture content of the curds, 0–30% of the rennet added to the milk is retained in the curd.
- *Indigenous milk enzymes*: These are particularly important in raw-milk cheese but many indigenous enzymes are sufficiently heat stable to withstand HTST pasteurisation. Important indigenous enzymes include plasmin, xanthine oxidase, acid phosphatase and, in raw-milk cheese, lipoprotein lipase. Information on the significance of other indigenous enzymes is lacking.
- *Starter LAB and their enzymes*: These reach maximum numbers (approximately 10^9 CFU/g) at the end of curd manufacture (6–12 hours). They then die and lyse at strain-dependent rates, releasing their intracellular enzymes.

Table 25.4. Changes in Cheese During Ripening

Softening of the Texture, due to:
- Proteolysis of the protein matrix, the continuous solid phase in cheese
- Increase in pH due to the catabolism of lactic acid and/or production of NH_3 from amino acids
- Migration of Ca to the surface in some cheeses, e.g. Camembert

Decrease in Water Activity, due to:
- Uptake of NaCl
- Loss of water through evaporation
- Production of low molecular weight compounds
- Binding of water to newly formed charged groups, e.g., $-NH_4^+$ or COO^-

Changes in Appearance, e.g.:
- Mould growth
- Colour, due to growth of *Brevibacterium linens*
- Formation of eyes

Flavour Development, due to:
- Formation of numerous sapid and aromatic compounds
- Release of flavourful compounds from the cheese matrix due to proteolysis

Changes in Functionality, e.g., Meltability, Stretchability, Water-Binding Properties, Browning, due to:
- Proteolysis
- Catabolism of lactose

- *Non-starter LAB (NSLAB)*: These are adventitious LAB that contaminate the cheese milk at farm and/or factory. Traditionally, cheesemakers relied on NSLAB for acid production during curd manufacture; this is still the case with some minor artisanal varieties but starter LAB are now used in all factory and most artisanal cheesemaking operations. Most NSLAB are killed by HTST pasteurisation and curd made from good-quality pasteurised milk in modern enclosed equipment has only a few hundred NSLAB, mainly mesophilic lactobacilli, per gram at the start of ripening. Indeed, only a limited number of species of mesophilic lactobacilli grow in cheese curd. However, those NSLAB that are present, grow at a rate depending mainly on the temperature to 10^7–10^8 cfu/g within about 3 months. In cheese made from raw milk, the NSLAB microflora is more diverse and reaches a higher number than in cheese made from pasteurised milk; the difference is probably mainly responsible for the more intense flavour of the former compared to the latter. This situation applies to all cheese varieties that have been investigated and the NSLAB dominate the viable microflora of cheese ripened for >2 months.
- *Secondary cultures*: Most cheese varieties develop a secondary microflora, which was originally adventitious but now develops mainly from added cultures. Examples are *Propionibacteria freudenrichii* subsp. *shermanii* (Swiss cheeses), *Penicillium roqueforti* (Blue cheeses), *Penicillium camemberti* and *Geotrichium candidum* (Camembert and Brie), *Brevibacterium linens, Arthrobacter* spp.,

Corynebacterium and yeasts (surface smear-ripened cheese) and citrate-positive *Lc. lactis* and *Leuconostoc* spp. (Dutch-type cheeses). Most of the microorganisms used as secondary cultures are very active metabolically and many secrete very active proteolytic and lipolytic enzymes. Consequently, they dominate the ripening of varieties in which they are used. Traditionally, a secondary culture was not used for Cheddar-type cheese but it is becoming increasingly common to add an adjunct culture, usually selected mesophilic lactobacilli (equivalent to adding a NSLAB population), to accelerate ripening, intensify flavour and perhaps tailor-make flavour. Essentially, the objective is to reproduce the microflora, and consequently the flavour, of raw-milk cheese. It is also becoming more common to add *Str. thermophilus* as an adjunct culture for Cheddar cheese.
- *Exogenous enzymes*: For some varieties of Italian cheese, for example Provalone and Pecorino varieties, rennet paste is used as coagulant. The rennet paste contains a lipase, PGE, in addition to chymosin; PGE is responsible for extensive lipolysis and the characteristic piquant flavour of the cheese. Rennet extract used for most varieties lacks PGE.

During ripening, a very complex series of reactions, which fall into three groups, occur:

1. Glycolysis of lactose and modification and/or catabolism of the resulting lactate
2. Lipolysis and the modification and catabolism of the resulting fatty acids
3. Proteolysis and catabolism of the resulting amino acids

Glycloysis and Related Events Fresh cheese curd contains approximately 1% lactose, which is converted to lactic acid (mainly the L-isomer) by the starter LAB, usually within 24 hours. Depending on the variety, the L-lactic acid is racemised to DL-lactic acid by NSLAB, or catabolised to CO_2 and H_2O in mould-ripened and in smear-ripened cheese. In Swiss-type cheese, lactic acid is converted to propionic and acetic acids, CO_2 and H_2O by *P. freudenrichii* subsp. *shermanii*; the CO_2 is responsible for the characteristic eyes in such cheese.

Lipolysis Little lipolysis occurs in most cheese varieties, in which it is catalysed by the weakly-lipolytic LAB or NSLAB, and indigenous milk lipase if raw milk is used. Extensive lipolysis occurs in some hard Italian-type cheeses, for example Provalone and Pecorino varieties, for which PGE is responsible, and in Blue cheese, for which *P. roqueforti* is responsible. Fatty acids are major contributors to the flavour of Provalone and Pecorino cheese and some may be converted to lactones or esters, which have characteristic flavours. In blue-veined cheese, fatty acids are converted to methyl ketones by *P. roqueforti* and these are mainly responsible for the characteristic peppery taste of such cheese. Some of the methyl ketones may be reduced to secondary alcohols.

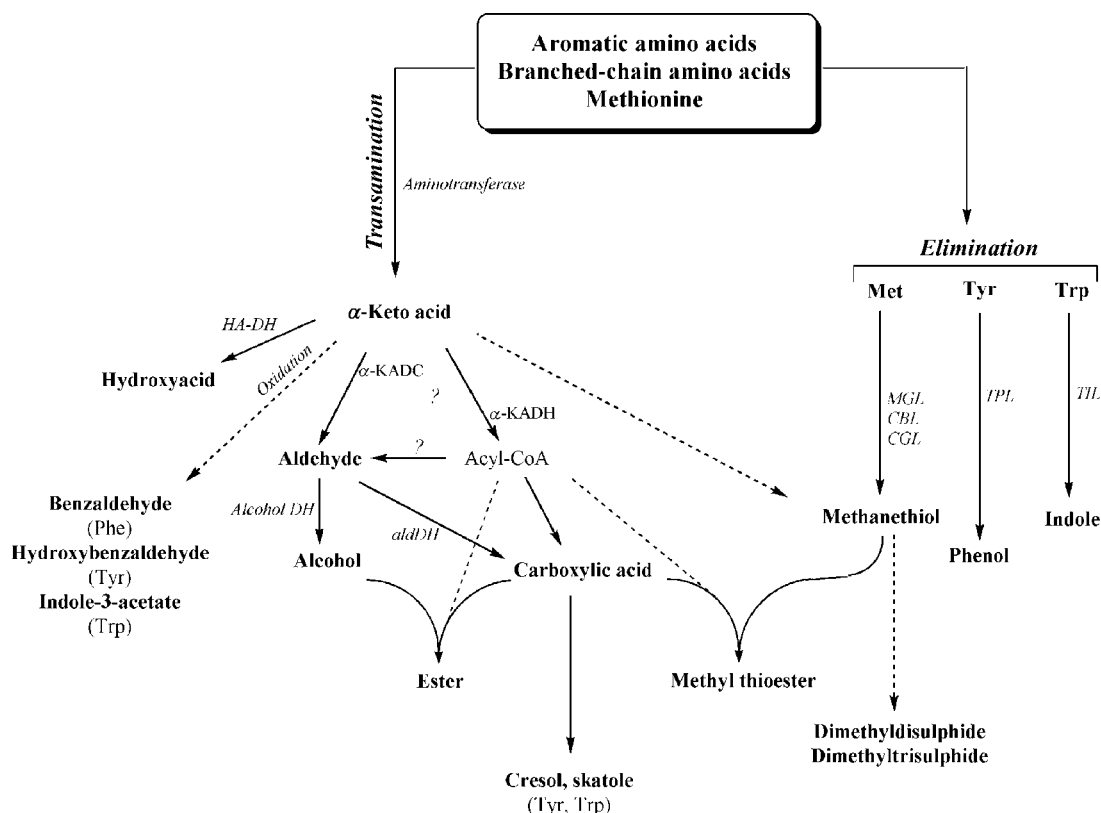
Proteolysis Proteolysis is the most complex and probably the most important of the three primary ripening reactions for the quality of cheese, especially internal bacterially ripened


Figure 25.3. Summary of amino acid catabolism during cheese ripening. MGL, methionine-γ-lyase; CBL, cystathionine-β- lyase; CGL, cystathionine-γ-lyase; TPL, tyrosine-phenol lyase; aldDH, aldehyde dehydrogenase; KADH, α-keto acid dehydrogenase; HADH, hydroxyl acid dehydrogenase; α−KADC, α−keto acid decarboxylase. (From Curtin and McSweeney 2004).

varieties. Initially, the caseins are hydrolysed by chymosin and, to a lesser extent by plasmin, in the case of β-casein; chymosin is almost completely inactivated in high-cook varieties and in this case plasmin is the principal agent of primary proteolysis. The polypeptides produced by chymosin or plasmin are too large to affect flavour, but primary proteolysis has a major influence on the texture and functionality of cheese. The peptides produced by chymosin or plasmin are hydrolysed to smaller peptides and amino acids by proteinases and peptidases of starter LAB and NSLAB. Small peptides contribute positively to the background brothy flavour of cheese but some are bitter. Many amino acids also have a characteristic flavour but, more importantly, they serve as substrates for a great diversity of catabolic reactions catalysed by enzymes of LAB, NSLAB and the secondary culture. The flavour of internal bacterially ripened cheese is probably mainly due to compounds produced from amino acids (Fig. 25.3).

Acceleration of Cheese Ripening

As the cost of storing cheese under controlled conditions for ripening represents a significant proportion of the cost of man-

ufacturing cheese, there have been many studies on factors that could accelerate the process of cheese ripening, that is achieve the desired texture and flavour in a shorter time. Key strategies that have been studied include increasing ripening temperature, manipulating starter or adding adjunct starter culture (e.g., increasing level of addition, or accelerating the rate at which starter cells lyse and release their enzymes into the cheese curd) and use of exogenous enzymes. Of these, the simplest is increasing ripening temperature (e.g., from 7°C for Cheddar to 13°C), which has been shown to increase rates of lipolysis and proteolysis. For the use of exogenous enzymes, the key is to get even distribution of enzyme in the cheese, which can most easily be achieved by adding enzymes to the cheese milk; however, much of the added enzyme is then lost in the whey. A general consideration applying to all methods for accelerating cheese ripening is that the overall balance of flavour should remain comparable to the reference product, which can be difficult to achieve.

Cheese-Related Products

In addition to the many types of natural cheese, as introduced previously, there is also a range of cheese-derived or substitute

products, such as processed cheese, cheese analogues and enzyme-modified cheese (EMC). Processed cheese is produced by blending natural cheeses of differing stages of ripening, to balance structural and flavour properties, and adding water and emulsifying salts that convert the insoluble calcium para-caseinate to more soluble and amphiphilic sodium para-caseinate, which then produces a stable emulsion. Emulsification is carried out under high-shear conditions at 70–90°C, yielding a safe and stable product. Following this molten stage, the cheese can be set (on cooling) into a wide range of shapes and forms, including blocks and slices; in addition, by choosing the formulation and ingredients used, a range of textures from solid blocks to spreads, which can have a range of added food components and flavours, can be produced.

In the case of cheese analogues, natural cheese is not used, and the main source of casein is usually rennet casein; such products may be used as Mozzarella substitutes for pizza toppings. EMC is cheese curd that has been incubated with enzymes (e.g., proteinases, peptidases and lipases) to yield a concentrated product with an intense cheese flavour that can be used as an ingredient (often in dried form) in food formulations. EMC with flavour profiles matching different cheese varieties have been produced.

Acid-Coagulated Cheeses

Acid-coagulated cheeses are at one end of the spectrum of fermented dairy products, the production of which is summarised in Figure 25.2A. Depending on the desired fat content of the final product, the starting material may be low-fat cream, whole milk, semi-skimmed milk or skimmed milk. The milk for Cottage-type cheese is subjected to only mild heat treatment so that the syneretic properties of the coagulum are not impaired.

Fermented Milks

In addition to acid-coagulated cheese, a wide range of fermented milk products are produced worldwide today, including:

- products of fermentation by mesophilic or thermophilic LAB (e.g., yoghurt); and
- products obtained by alcohol-lactic fermentation by LAB and yeast (e.g., kefir, koumiss).

For yoghurt, as for acid-coagulated cheese, the milk base (with a fat content depending on the final product) is usually supplemented with milk solids to enhance the viscosity and rigidity of the final coagulum, in some cases to simulate the viscosity of yoghurt made from sheep's milk, which has a higher total solids content than cows' milk. The milk solids added may be WMP or SMP or whey powders, depending on the type of product required (González-Martínez et al. 2002, Remeuf et al. 2003). The most commonly used milk powder today is probably SMP, typically of medium heat classification. Buttermilk powder may be used also as a substitute for SMP, with the advantages of good emulsifying properties and potential biological activity.

Syneresis, which causes free whey in the product, is very undesirable in fermented milk products. Therefore, the milk or starting mix is subjected to a severe heat treatment (e.g., 90°C for 10 minutes) to denature the whey proteins, increase their water-binding capacity and produce a firmer gel network, consisting of casein–whey protein complexes. The heat treatment also kills vegetative pathogenic bacteria, rendering the product safe (Robinson 2002a). Homogenisation of the mix also increases the firmness of the gel, because the fat globules in homogenised milk are stabilised mainly by a surface layer of adsorbed casein micelles, through which they can become structural elements of the final acid-induced gel.

The relative proportion of caseins and whey proteins in yoghurt has a significant influence on the structure of the gel (Puvanenthiran et al. 2002). Hydrocolloid stabilisers (polysaccharides or proteins) may be added to the mix to modify the viscosity (by gelling or thickening) and/or prevent syneresis (Fizsman et al. 1999, Tamime and Robinson 1999). Pectin is probably the most commonly used hydrocolloid stabiliser for yoghurt, but carageenan, guar gum, alginate and various modified and natural starches are also widely used. Sweetening agents (e.g., sugars or synthetic sweeteners such as aspartame) may be added to the mix, and fruit purees or fruit essence may be added either at the start or end of fermentation.

The starter culture for yoghurt contains *Str. thermophilus* and *Lb. bulgaricus* subsp. *bulgaricus*. In recent years, many fermented milk products have been introduced with added probiotic bacteria such as *Bifidobacteria* spp. or *Lactobacillus acidophilus,* due to increasing consumer interest in the health benefits of such bacteria, and increasing clinical evidence of their efficacy (Surono and Hosono 2002, Robinson 2002b, Reid 2008, Sanchez et al. 2009). The texture and viscosity of yoghurt may be modified by using an exopolysaccharide (EPS)-producing starter culture (strains of both *Str. thermophilus* and *Lb. bulgaricus* subsp. *bulgaricus* have been identified that secrete capsular heteropolysaccharides; De Vuyst et al. 2001, Hassan et al. 2003).

During fermentation, the production of lactic acid destabilises the casein micelles resulting in their coagulation (acid-induced gelation) (Lucey and Singh 1998). The main point of difference between the production protocols for yoghurt and acid-coagulated cheese is that when the pH has reached 4.6 and the milk has set into a coagulum, this coagulum is cut or broken for the latter but not for the former. In addition, the heat treatment applied to milk for the manufacture of acid-coagulated cheese is less severe than for yoghurt, to facilitate syneresis in the former, while avoiding it in the latter.

Depending on the desired characteristics of the finished product, the milk may be fermented in the final package (to produce a firm set yoghurt) or in bulk tanks, followed by filling (to produce a more liquid stirred yoghurt) (Tamime and Robinson 1999, Robinson 2002a). The rate of acidification for set or stirred yoghurt differs due to differences in the level of inoculation and incubation temperature.

It is important to cool the yoghurt rapidly when pH 4.6 is reached, to preserve the gel structure and prevent further starter activity (Robinson 2002a). In some cases, the viscosity of the yoghurt may be reduced by post-fermentation homogenisation to produce drinking yoghurt.

Yoghurt has a relatively short shelf life; common changes during storage involve syneresis, with whey expulsion, and

further slow acidification by starter bacteria. To prevent the latter, and thereby extend the shelf life of yoghurt, the final product may be pasteurised after acidification; to prevent damage to the gel structure at this point, the role of hydrocolloid or protein stabilisers is critical (Walstra et al. 1999).

Acid-Heat Coagulated Cheeses

These cheeses were produced initially in Southern European countries from whey as a means of recovering nutritionally valuable whey proteins; their production involves heating whey from rennet-coagulated cheese to approximately 90°C to denature and coagulate the whey proteins. Well-known examples are Ricotta and Manouri. Today, such cheeses are made from blends of milk and whey, and in this case, it is necessary to adjust the pH of the blend to approximately 5.2 using vinegar, citrus juice or fermented milk.

Acid-heat coagulated cheese may also be produced from whole milk by acidifying to pH 5.2 and heating to 90°C, for example US-style Queso Blanco, which does not melt on heating and hence has interesting functional properties for certain applications.

WHEY PROCESSING

RANGE OF WHEY PRODUCTS

For many centuries, whey was often viewed as an unwanted and valueless by-product of cheese manufacture; however, since around 1970, whey has been repositioned as a valuable source of a range of food ingredients, rather than a disposal problem. While part of the impetus for this strategic re-evaluation of the potential of whey was driven by environmental and other concerns about the disposal of a product of such a high Biological Oxygen Demand, it has resulted in a previously unsuspected richness and diversity of products, and a significant new processing sector of the dairy industry (Sienkiewicz and Riedel 1990, Jelen 2002).

The first stage in the production of any whey product is preliminary purification of the crude whey, recovered after cheese or casein manufacture. Fresh whey is classified as either sweet, with a pH > 5.6 and a low calcium content, or acid whey, with a pH of around 4.6 and high calcium content; the difference in calcium content arises from the solubilisation of colloidal calcium phosphate as the pH of the milk decreases. Common pre-treatments include centrifugal clarification to remove curd particles (fines), and pasteurisation (to inactivate starter LAB). For many whey protein-based products, removal of all lipids is desirable; this can be achieved by centrifugal separation to produce whey cream, which may be churned into whey butter. To obtain a very low level of lipids, calcium chloride may be added to the whey, with adjustment of the pH to more alkaline values, followed by heating and cold storage to precipitate and remove lipoprotein complexes (thermocalcic aggregation; Karleskind et al. 1995).

The next level of processing technology applied to the pre-treated whey depends on the end product to be manufactured.

The simplest whey products are probably whey beverages, consisting of clarified whey, typically blended with natural or concentrated fruit juices. Whey beverages have a nutritionally beneficial amino acid profile; although not widely commercialised, such drinks have been successful in some European countries (e.g., Rivella in Switzerland).

Whey may be concentrated by evaporation and spray-dried to whey powders. The key consideration in spray-drying whey is the constraints imposed by the fact that the major constituent of whey is lactose (typically, >75% of whey solids). Thus, processes for drying whey must include controlled crystallisation of lactose to yield small crystals (30–50 μm). This is typically achieved by controlled cooling of concentrated (i.e., supersaturated with respect to lactose) whey under a programmed temperature regime, with careful stirring and addition of seed crystals, typically of α-lactose monohydrate, followed by holding under conditions sufficient to allow crystallisation to proceed. In general, only approximately 70% of the lactose present will crystallise at this stage, and processes often include a post-drying crystallisation stage, for example on a belt attached to the spray-dryer, where the remainder crystallises.

The simplest dried whey product is whey powder, which is produced in a single-stage spray-dryer. Additional care must be taken in drying acid whey products, which may be sticky; the corrosive nature of the acids (e.g., HCl) used in their manufacture may also present processing difficulties and such products may be neutralised prior to drying.

Whey powders may be unsuitable for use in certain food applications (e.g., infant formulae) due to their high mineral content; in such cases, whey is demineralised by ion exchange or electrodialysis before concentration and dialysis (for a discussion of the technologies involved, see Burling 2002). Demineralisation of whey is also desirable for use in ice cream production, to reduce the salty taste of normal whey powder.

WHEY-PROTEIN-RICH PRODUCTS

Whey powder has a low (approximately 12–15%) protein content and a high (approximately 75%) lactose content; many whey products have been at least partially purified to increase the level of a particular constituent, usually protein (Matthews 1984). There is a family of protein-enriched whey-derived powders, which are differentiated based on the level of protein; whey protein concentrates (WPCs) with a protein content in the range 35–80%, and whey protein isolates (WPIs) with a protein content >88%. Typically, WPCs are produced by UF, with protein being progressively concentrated in the retentate, while lactose, salts and water are removed in the permeate (Ji and Haque 2003). Higher protein levels can be achieved by diafiltration, that is, dilution of the retentate followed by UF. The use of ion exchangers to adsorb the proteins from whey, followed by selective release into suitable buffer solutions, is required to achieve the high degree of purity required of WPIs.

Methods for the purification of individual whey proteins have been developed, usually exploiting differences in the stability of individual proteins under specific conditions of pH, temperature and ionic salts. In addition, methods involving organic

extraction, selective enzymatic hydrolysis and ion-exchange resins have been described. On a commercial scale, the production of products containing purified but unfractionated whey proteins remains most common, although ion-exchange methods for the recovery of biologically significant (and hence high value) proteins from whey, such as lactoperoxidase and lactoferrin have been scaled up and are in commercial operation.

LACTOSE PROCESSING

Whey or whey permeate, produced as a by-product of UF processing, contains a high level of lactose. This can be recovered by crystallisation from a concentrated (supersaturated, 60–62% TS) preparation of either whey or whey permeate (for review see Muir 2002, Peterson 2009). The crystalline lactose is usually recovered using a decanter centrifuge, dried in a fluidised bed dryer and ground to a fine powder, which is used in food applications, for example confectionery products and infant formulae. Lactose is also used widely in pharmaceutical applications (e.g., as a diluent in drug tablets); for such applications, the lactose is generally further refined by re-dissolving in hot water and mixing with activated carbon, followed by filtration, crystallisation and drying.

Many derivatives of lactose can be produced, some of which are more valuable and useful than lactose (Fig. 25.4, Playne and Crittenden 2009). For example, lactulose (β-D-galactosyl-D-fructose) and lactitol (β-D-galactosyl-sorbitol) are used in treatment of patients with chronic hepatic encephalopathy, and both have prebiotic effects. In addition, lactose in whey can be fermented to alcohol for industrial use in beverages.

CASEINS: ISOLATION, FRACTIONATION AND APPLICATIONS

In recent years, it has been increasingly recognised that milk proteins have functionalities that can be exploited in food systems other than conventional dairy products; these proteins have

Figure 25.4. Food-grade derivatives of lactose.

been increasingly recognised as desirable ingredients for a range of food products (Mulvihill and Ennis 2003). The very different properties of the two classes of milk proteins, the caseins and whey proteins, present different technological challenges for recovery, and are suitable for quite different applications. The whey proteins have been discussed previously, and the caseins will be discussed in the following section.

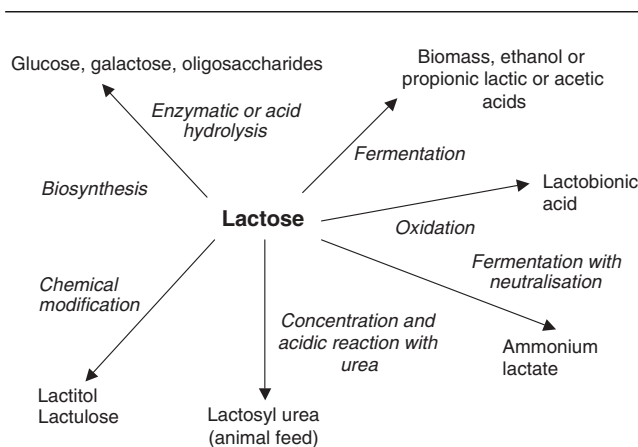
RECOVERY AND APPLICATION OF CASEINS

Technologies for the recovery of caseins from milk are based on the fact that relatively simple perturbations of the milk system can destabilise the caseins selectively, resulting in their precipitation and facilitating their recovery from milk (Mulvihill and Fox 1994, Mulvihill and Ennis 2003). As discussed for rennet-coagulated cheese, the stability of the caseins in a colloidal micellar form is possible due to the amphiphilic nature of κ-casein. To overcome this stability, and precipitate the caseins, merely requires that this stabilising effect be overcome.

The two key principles used to destabilise the micelles are (1) acidification to the isoelectric point of the caseins (pH 4.6) or (2) limited proteolysis, for example by chymosin, which hydrolyses κ-casein, removing the stabilising glycomacropeptide. In both cases, the starting material for casein production is skim milk. For acid casein, acidification can be achieved either by addition of a mineral acid, usually HCl, or fermentation of lactose to lactic acid by a culture of LAB. When the isoelectric point is reached, a precipitate (rapid acidification) or a gel (slower acidification) is formed; the latter is cut/broken to initiate syneresis and expel whey. The mixture of casein and whey is stirred and cooked to enhance syneresis, and the casein separated from the whey (either centrifugally or by sieving). To improve the purity of the casein, the curds are washed repeatedly with water to remove residual salts and lactose, and the final casein is dried, typically in specialised dryers, such as attrition or ring dryers. For rennet casein, the milk gel is formed by adding a suitable coagulant to skim milk, but subsequent stages are similar to those for acid casein.

Both acid and rennet casein are relatively insoluble in water, and are used in the production of cheese analogues (rennet casein) and convenience food products, as well as non-food applications, such as the manufacture of glues, plastics and paper glazing (acid casein).

To extend the range of applications of acid casein, and improve its functionality, it may be converted to a metal salt (e.g., Na, K, Ca caseinates), by mixing a suspension of acid casein with the appropriate hydroxide and heating, followed by drying (typically with a low, that is approximately 20%, total solids concentration in the feed, due to high product viscosity, in a spraydryer). Caseinates, particularly sodium caseinate, have a range of useful functional properties, including emulsification and thickening; calcium caseinate has a micellar structure (Mulvihill and Ennis 2003).

Microfiltration (MF) technology may be used to produce powders enriched in micellar casein (Pouliot et al. 1996, Maubois 1997, Kelly et al. 2000, Garem et al. 2000). Casein recovered by MF has very different functionality and properties compared


to acid or rennet casein, and may be more suitable for use in applications such as cheese manufacture, as it closely resembles the micellar casein in milk.

Whole casein may be resolved into β- and α_s/κ-casein-rich fractions by processes that exploit the dissociation of β-casein at a low temperature (reviewed by Mulvihill and Ennis 2003), or low-temperature dissociation after renneting of milk (Huppertz et al. 2006). Chromatographic or precipitation processes can be used to purify the other caseins, although such processes are generally not easy to scale up for industrial-level production (Coolbear et al. 1996, Farise and Cayot 1998).

EXOGENOUS ENZYMES IN DAIRY PROCESSING

The dairy industry represents one of the largest markets for commercial enzyme preparations. The use of some enzymes in the manufacture of dairy products, for example rennet for the coagulation of milk, is in fact probably the oldest commercial application of enzyme biotechnology.

PROTEINASES

The use of rennets to coagulate milk and the ripening of cheese, were discussed earlier. A further application of proteolytic enzymes in dairy products, that is the production of dairy protein hydrolysates, is discussed later in this chapter. The applications of other enzymes of significance for dairy products are discussed in this Section.

β-GALACTOSIDASE

Hydrolysis of lactose (4-O-β-D-galactopyranosyl-D-glucopyranose), either at a low pH or enzymatically (by β-galactosidases), yields two monosaccharides, D-glucose and D-galactose (Mahoney 1997, 2002). A large proportion of the world's population suffers from lactose intolerance, leading to varying degrees of gastrointestinal distress if lactose-containing dairy products are consumed. However, glucose and galactose are readily metabolised; they are also sweeter than lactose. Glucose/galactose syrups are one of the simplest and most common commercial products of lactose hydrolysis.

β-Galactosidases is available from several sources, including *E. coli, A. niger, Aspergillus oryzae and K. lactis* (Whitaker 1994; Mahoney 2002, Husain 2010). β-Galactosidase for use in dairy products must be isolated from a safe source and be acceptable to regulatory authorities; for this reason, genes for some microbial β-galactosidases have been cloned into safe hosts for expression and recovery. Of particular interest are enzymes that are active either at a low or a very high temperature, to avoid the microbiological problems associated with enzymatic treatment at temperatures that encourage the growth of mesophilic microorganisms (Vasiljevic and Jelen 2001). Microorganisms capable of producing thermophilic β-galactosidases include *Lb. bulgaricus* subsp. *bulgaricus* (Vasiljevic and Jelen 2001) and *Thermus thermophilus* (Maciunska et al. 1998), while cold-

active β-galactosidase has been purified from psychrophilic bacteria (Nakagawa et al. 2003).

Enzymatic hydrolysis of lactose rarely leads to complete conversion to monosaccharides, due to feedback inhibition of the reaction by galactose, as well as concurrent side-reactions (due to transferase activity) that produce isomers of lactose and oligosaccharides (Chen et al. 2002). While initially considered to be undesirable by-products of lactose hydrolysis, galacto-oligosaccharides are now recognised to be bifidogenic factors, which enhance the growth of desirable probiotic bacteria in the intestine of consumers and suppress the growth of harmful anaerobic colonic bacteria (Shin et al. 2000).

Lactose has a number of other properties that cause difficulty in the processing of dairy products, such as its tendency to form large crystals on cooling of concentrated solutions of the sugar; lactose-hydrolysed concentrates are not susceptible to such problems. For example, hydrolysis of lactose in whey concentrates can preserve these products through increased osmotic pressure, while maintaining physical stability (Mahoney 1997, 2002).

For the hydrolysis of lactose in dairy products, β-galactosidase may be added in free solution, allowed sufficient time to react at a suitable temperature and inactivated by heating the product. To control the reaction more precisely and avoid uneconomical single use of the enzyme, immobilised enzyme technology (e.g., where the enzyme is immobilised on an inert support, such as glass beads) or systems where the enzyme is recovered by UF of the product after hydrolysis and reused have been studied widely (Obon et al. 2000). A further technique with potential for application in lactose hydrolysis is the use of permeabilised bacterial or yeast cells (e.g., *K. lactis*) with β-galactosidase activity. In such processes, the cells are treated with agents, for example ethanol, to damage their cell membrane and allow diffusion of substrate and reaction products across the damaged membrane; the cell itself becomes the immobilisation matrix and the enzyme is active in its natural cytoplasmic environment (Fontes et al. 2001, Becerra et al. 2001). This provides a crude but convenient and inexpensive enzyme-utilisation strategy. Overall, however, few immobilised systems for lactose hydrolysis are used commercially, due to technological limitations and high cost of such processes (Zadow 1993); one strategy of potential interest involves the recovery of soluble enzyme by UF, allowing separation from the product and substrate, and recovery and reuse of the enzyme.

One of the more common applications of lactose hydrolysis is the production of low-lactose liquid milk, suitable for consumption by lactose-intolerant consumers; this may be achieved in a number of ways, including adding a low level of β-galactosidase to packaged UHT milk, or the consumer may add β-galactosidase to milk during domestic refrigerated storage (Modler et al. 1993). In the case of ice cream, lactose hydrolysis reduces the incidence of sandiness (due to lactose crystallisation) during storage and, due to the enhanced sweetness, permits the reduction of sugar content. Lactose hydrolysis may also be applied in yoghurt manufacture, to make reduced-calorie products.

Overall, despite considerable interest, industrial use of lactose hydrolysis by β-galactosidases has not been widely adopted,

although such processes have found certain niche applications (Zadow 1993).

Transglutaminase

Transglutaminases (TGase; protein-glutamine: amine γ-glutamyl-transferase) are enzymes that create inter- or intramolecular cross-links in proteins by catalysing an acyl-group transfer reaction between the γ-carboxyamide group of peptide-bound glutamine residues and the primary amino group of lysine residues in proteins. TGase treatment can modify the properties of many proteins through the formation of new cross-links, incorporation of amines or deamidation of glutamine residues.

TGases are widespread in nature; for example blood factor XIIIa, or fibrinoligase, is a TGase-type enzyme, and TGase-mediated cross-linking is involved in cellular and physiological phenomena such as cell growth and differentiation, as well as blood clotting and wound healing. TGases have been identified in animals, plants and microbes (e.g., *Streptoverticillium mobaraense*, which is the source of much of the TGase used in food studies). TGase may be either calcium-independent (most microbial enzymes) or calcium-dependent (typical for mammalian enzymes).

TGase-catalysed cross-linking can alter the solubility, hydration, gelation, rheological and emulsifying properties, rennetability and heat stability of a variety of food proteins (Motoki and Seguro 1998). The structure of individual proteins determines whether cross-linking by TGase is possible. Caseins are good substrates for TGase due to their open structure but the whey proteins, due to their globular structure, require modification, for example heat-induced denaturation, to allow cross-linking (Ikura et al. 1980, Sharma et al. 2001, O'Sullivan et al. 2002a, b). When the whey proteins in milk are in the native state, the principal cross-linking reactions involve the caseins; heat-induced denaturation renders the whey proteins susceptible to cross-linking, both to each other and to casein molecules.

TGase treatment has several significant effects on the properties of milk and dairy products. For example, TGase treatment of fresh raw milk increases its heat stability; if milk is pre-heated under conditions that denature the whey proteins prior to TGase treatment, the increase in heat stability is even more marked (O'Sullivan et al. 2002a). This is probably due to the formation of cross-links between the caseins and denatured whey proteins, brought into close proximity by the formation of disulphide bridges between β-lg and micellar κ-casein. There has also been considerable interest in the effects of TGase treatment on the cheesemaking properties of milk, in part due to the potential for increasing cheese yield. It has been suggested that TGase treatment of milk before renneting can achieve this effect. However, a number of studies (Lorenzen 2000, O'Sullivan et al. 2002a) have indicated that the rennet coagulation properties of milk and the syneretic properties of TGase-cross-linked renneted milk gels, as well as the proteolytic digestibility of casein, are impaired by cross-linking the proteins, which may alter cheese manufacture and ripening. Further studies are required to evaluate whether limited, targeted cross-linking may give desirable effects.

Other potential benefits of TGase treatment of dairy proteins include physical stablilisation and structural modification of products such as yoghurt, cream and liquid milk products, particularly in formulations with a reduced fat content, and the production of protein products, such as caseinates or whey protein products, with modified or tailor-made functional properties (Dickinson and Yamamoto 1996, Lorenzen and Schlimme 1998, Færgamand and Qvist 1998, Færgamand et al. 1998).

Overall, it is likely that TGase will have commercial applications in modifying the functional characteristics of milk and dairy products. However, some important issues remain to be clarified; for example the heat inactivation kinetics of the enzyme, to facilitate control of the reaction through inactivation at the desired extent of cross-linking. There is also a dearth of information on the effects of processing variables (e.g., temperature, pH) on the nature and rate of cross-linking reactions. Finally, a clear commercial advantage of using TGase over other methods for manipulating the structure and texture of dairy products (such as addition of proteins or hydrocolloids) must be established.

Lipases

Lipases, that is enzymes that produce free fatty acids (FFAs) and flavour precursors from triglycerides, diglycerides and monoglycerides, are produced by a wide range of plants, animals and microorganisms (Kilara 2003). For example, calves produce a salivary enzyme called PGE, which is present at high levels in the stomachs of calves, lambs or kids slaughtered immediately after suckling (Kilcawley et al. 1998). Microbial lipases have been isolated from *A. niger*, *A. oryzae*, *Pseudomonas fluorescens* and *P. roqueforti*. Exogenous lipases may be used for a range of applications (Kilara 2011), including:

- modification of milk fat to improve its physical properties and digestibility, reduce calorific value and enhance flavour (Balcão & Malcata 1998);
- production of EMC flavours (e.g., 'buttery', 'blue cheese' or 'yoghurt'); and
- production of lipolysed creams for bakery applications.

The correct choice of lipase for particular applications is very important, as the FFA profile differs with the type of enzyme used, and different lipases vary in their pH and temperature optima, heat stability and other characteristics. Calf PGE, for example generates a buttery and slightly peppery flavour, while kid PGE generates a sharp peppery flavour (Birsbach 1992).

The intense flavour of blue cheese results from lipolysis and catabolism of FFAs; most other cheese varieties undergo very little lipolysis during ripening. A method for the production of blue cheese flavour concentrates was described by Tomasini et al. (1995). It has been reported that the use of exogenous lipases (e.g., PGE) can enhance the flavour of Cheddar cheese and accelerate the development of perceived maturity (for review see Kilcawley et al. 1998). EMC preparations (e.g., slurries or powders) can also be produced by incubation of cheese emulsified in water with commercial enzymes (such as those produced by Novo Nordisk) that have 5–20 times the flavour intensity of mild Cheddar cheese.

Other Enzymes

Other enzymes that have been used in dairy processing include catalase, lactoperoxidase and lysozyme. All of these are added for preservative reasons, and their use is more common in some countries than others. Lysozyme may be added to milk for making certain cheese varieties (e.g., Edam, Emmental) to prevent growth of *Clostridium tyrobutyricum* and gas blowing, although its use is not widespread. Catalase and lactoperoxidase may be used in milk preservation strategies (particularly in tropical countries), with the latter (either the indigenous activity present or added purified enzyme) acting on hydrogen peroxide (which may be added to the milk) and the former being used to destroy excess hydrogen peroxide and terminate the enzymatic reaction (Brennan and McSweeney 2011).

MILK LIPIDS

Production of Fat-Based Dairy Products

Milk fat is a complex mixture of triglycerides that, in milk, is maintained as a stable o/w emulsion by the MFGM, which surrounds milk fat globules and protects the lipids therein from physical or enzymatic damage.

As mentioned earlier, separation of milk, either slowly under the influence of gravity or more rapidly under centrifugal force, readily produces a fraction (cream) enriched in the less dense milk fat globules, separated from the fat-depleted skim milk. Cream products of varying fat content (12–40%) are produced industrially for a range of applications, including dessert, coffee and as a food ingredient. The technology of cream products was reviewed by Smiddy et al. (2009).

One of the oldest dairy products is butter, a fat-continuous (water-in-oil, w/o) emulsion containing 80–81% fat, not more than 16% H_2O and, usually, 1.5% added salt. The production of butter from cream requires destabilisation of the emulsion and phase inversion, followed by consolidation of the fat and removal of a large part of the aqueous phase (Frede and Buchheim 1994, Frede 2002a). The manufacture of butter has been the subject of several reviews (e.g., Keogh 1995, Lane 1998; Ranjith and Rajah 2001, Frede 2002a, Wilbey 2009).

In traditional butter manufacture, cream is churned (mixed) in a large partially filled rotating cylindrical, conical or cubical churn, which damages the MFGM. Mechanically damaged fat globules become adsorbed on the surfaces of air bubbles (flotation churning) and gradually coalesce, being bound together by expressed free fat, to form butter grains. Eventually, the air entrapped within such grains is expelled and churning generally progresses until the grains have grown to approximately the size of a pea (Frede and Buchheim 1994, Vanapilli and Coupland 2001). In a batch process, growth of grains is monitored visually and audibly (impact of masses of grains on the churn walls); at this point, the buttermilk (essentially, skim milk but with a high content of sloughed off MFGM components such as phospholipids) is drained off and the butter worked by repeated falls and impaction within the rotating churn. After a set time, salt is added and worked throughout the butter.

With the exception of very small-scale plants, most modern dairy factories use continuous rather than batch buttermakers. In the most common system, the Fritz system, each stage of the process occurs in a separate horizontal cylindrical chamber, with product passing vertically between stages. In the churning cylinder, rotating impellers churn the cream very rapidly in the first stage, and in the second stage, butter grains are consolidated and the buttermilk drained off. In the final stage, the butter mass is worked; this chamber is sloped upwards and, while augers transport the butter and squeeze it through a series of perforated plates, the buttermilk drains off in the opposite direction. Midway through the working stage, salt (generally as a concentrated brine) is added, and becomes distributed in small moisture droplets with a high local salt concentration (~12.5% S/M), which acts to flavour and microbiologically stabilise the butter. The moisture present in the final droplets comes originally from milk serum, with a small contribution from water added in brine.

The by-product buttermilk is rich in MFGM materials, including phospholipids, and is commonly dried and used as an ingredient in many food products; however, due to its high content of polyunsaturated fatty acids, it deteriorates quite rapidly due to oxidation (O'Connell and Fox 2000). In recent years, there has been increasing interest in the fact that buttermilk contains high levels of biologically active (e.g., anticarcinogenic, anticholesterolemic) membrane-derived lipids, including glycosphingolipids and gangliosides (Jensen 2002, Dewettinck et al. 2008). Buttermilk isolates may also have potential application as emulsifying agents (Corrideg and Dalgleish 1997, Singh 2006). In addition, proteins in the MFGM such as butyrophilin may have anticancer and antimicrobial properties, and may play a role in diseases including multiple sclerosis and autism (Dewettinck et al. 2008).

Traditionally, butter was produced from cream that was naturally soured, and, today, in some countries, cream for butter manufacture is ripened with LAB (lactic or fermented butter). Bacterial acidification enhances the keeping quality of butter and changes the flavour, through production of diacetyl. However, the production of lactic butter leads to the production of acidic buttermilk as an unwanted by-product, and in recent years alternative technologies have been developed for the production of lactic butter. One of the most successful is the NIZO method, in which a sweet (non-lactic) cream is used, and a concentrated starter permeate is added to the butter grains midway through the process. This process leads to production of normal buttermilk, gives a well-flavoured product, which is very resistant to autoxidation (Walstra et al. 1999).

In the second half of the nineteenth century, the high cost of butter led to the development of alternatives to butter, such as margarine; consumer preference for reduced-fat (i.e., higher perceived 'healthiness') products has strengthened this trend. A further significant disadvantage of butter for domestic applications is the fact that at typical refrigeration temperatures, butter behaves essentially as a solid and has poor spreadability; moreover, at room temperature, it oils off and exudes water. The spreadability of butter may be improved by blending with vegetable oils, or by modifications such as interesterification (Marangoni and Rousseau 1998).

Today, there are two principal classes of non-butter milk-fat based spreads; (1) full-fat products with partial replacement of milk fat by another (e.g., vegetable) fat, with physicochemical, rheological, economic or dietary advantage, and (2) reduced-fat products containing varying levels of milk fat (Frede 2002b). Such products may be manufactured either in a modified continuous buttermaking system (butter technology) or in a votator scraped-surface cooler system (margarine technology). Generally, all products are made by preparation of aqueous (e.g., skim milk or cream) and lipid phases, each containing the appropriate ingredients, followed by mixing and phase inversion of the initial o/w emulsion to a final w/o emulsion. Reduction of the fat content of the mix requires increased attention to the structural characteristics of the aqueous phase, which must increasingly contribute to the texture and body of the product. Aqueous phase structuring agents, such as polysaccharides and/or proteins, may be added for this purpose (Keogh 1995, Frede 2002b).

Butter is a relatively stable product; the small size and high salt content of the water droplets make them an inhospitable environment for microbial growth. Lower fat spreads, while also being generally stable products, may have preservatives, such as sorbates, incorporated into their formulation to ensure shelf life and safety (Delamarre and Batt 1999).

Some new developments in the technology of spreads include the production of triple-emulsion (o/w/o) products (in which the droplets of aqueous phase in the product contain very small fat globules) (Frede 2002b). These systems have three distinct phases, and need two or more emulsifiers and/or the use of proteins or polysaccharides as stabilisers/thickeners, as they can be quite unstable due to the presence of at least two interfaces (Kanouni et al. 2002, O'Regan and Mulvhill 2010).

Production and Fractionation of Milk Fat

The most purified form of milk fat commercially produced is anhydrous milk fat (AMF), which consists of >99% triglycerides, and is produced in many countries. The production of AMF requires the removal of water and water-soluble components of milk, and may be achieved either by successive high-speed centrifugation, with phase-inversion at high fat levels, or by starting with butter, which is melted and centrifuged to recover the purified fat phase. Lipid oxidation is a significant concern during AMF manufacture, and the presence of oxygen during the process must be avoided.

AMF may be fractionated to yield fractions of milk fat with different desirable properties (Illingworth et al. 2009), usually on the basis of melting point. The most common industrial processes for milk fat fractionation involve cooling melted milk fat to temperatures where crystallisation of some of the fat occurs, facilitating the removal of a high melting point fraction (stearin crystals) from the low melting point fraction (olein). This removal may be by centrifugation or filtration through plate-and-frame membrane units. This basic fractionation process may be improved through the use of detergents or solvents, such as acetone.

There are also a number of methods for removal of cholesterol from dairy products, either through enzymatic, microbial, chem-

ical (solid–liquid extraction, complexation) or physical means (distillation and crystallisation, supercritical fluid extraction). There have been several studies of the application of such methods for the removal of cholesterol from dairy products, including homogenised milk, butter and butter oil, and reduced-cholesterol dairy products have appeared on the marker since the 1990s; however, greater consumer preference for reduced-fat versus specifically reduced-cholesterol products may limit their widespread appeal (Sieber & Eyer 2011).

Lipid Oxidation

Lipids with double bonds (i.e., unsaturated fatty acids) are inherently susceptible to attack by active O_2, that is, lipid oxidation. Oxidation can give rise to a range of undesirable flavour compounds (such as aldehydes, ketones and alcohols that cause rancid off-flavours), and possibly result in toxic products. Oxidation is dependent on factors such as availability of oxygen, exposure to light, temperature, presence of pro- or anti-oxidants and the nature of the fat (O'Brien and O'Connor 1995, 2002, 2011).

Milk fat contains a high level of monounsaturated fatty acids (although less than many other fats), but a low level of polyunsaturated fatty acids. It is susceptible to oxidation but raw milk samples differ in susceptibility to oxidation as follows:

- *Spontaneous*: Will develop oxidised flavour within 48 hours without the addition of pro-oxidant metals, such as iron or copper
- *Susceptible*: Will not oxidise spontaneously, requires contamination by pro-oxidant metals
- *Non-susceptible*: Will not oxidise even in the presence of iron or copper

The reasons for the difference between milk samples are not clear, but are likely to be related to lactational and dietary factors, and the enzyme xanthine oxidase in milk may be critical.

Of particular current interest is the oxidation of the unsaturated alcohol, cholesterol, in milk; consumption of cholesterol oxidation products (COPs) in the diet is tentatively linked to the incidence of artherosclerosis (Kumar and Singhal 1991), and hence these products are regarded as potential health hazards. COPs are not found in all dairy product, but have been detected in WMP, baby foods, butter and certain cheese varieties, albeit at levels that probably do not pose a risk to consumers (Sieber et al. 1997, RoseSallin et al. 1997). The formation of COPs is influenced by factors such as temperature and exposure of the food to light (Angulo et al. 1997, RoseSallin et al. 1997, Hiesberger and Luf 2000).

Ice Cream

Ice cream, probably the most popular dairy dessert, is a frozen aerated emulsion. The continuous phase consists of a syrup containing dissolved sugars and minerals, while the dispersed phase consists of air cells, milk fat (or other kinds of fat) globules, ice crystals and insoluble proteins and hydrocolloids (Marshall 2002). The structure of ice cream is particularly complex, with several phases (e.g., ice crystals, fat globules and air

bubbles, freeze-concentrated aqueous phase) coexisting in a single product.

The production technology for ice cream was reviewed by Goff (2002 2011), and will be summarised briefly here. The base for production of ice cream is milk blended with sources of milk solids non-fat (e.g., SMP) and fat (e.g., cream), added sugars or other sweeteners, emulsifying agents and hydrocolloid stabilisers. The exact formulation depends on the characteristics of the final product and, once blended, the mix is pasteurised, by either batch (e.g., 69°C for 30 minutes) or continuous (e.g., 80°C for 25 seconds) processes, and homogenised at 15.5–18.9 MPa, first stage, and 3.4 MPa, second stage. The mix is then cooled and stored at 2–4°C for at least 4 hours; this step is called ageing, and facilitates the hydration of milk proteins and stabilisers, and crystallisation of fat globules. During this period, emulsifiers generally displace milk proteins from the milk fat globule surface. Ageing improves the whipping quality of the mix and the melting and structural properties of the final ice cream.

After ageing, the ice cream is passed through a scraped-surface heat exchanger, cooled using a suitable refrigerant flowing in the jacket, under high-shear conditions with the introduction of air into the mix. These conditions result in rapid ice crystal nucleation and freezing, yielding small ice crystals, and the incorporation of air bubbles, resulting in a significant increase in the volume (over-run) of the product. The partially crystalline fat phase at refrigeration temperatures undergoes partial coalescence during the whipping and freezing stage, and a network of agglomerated fat develops, which partially surrounds the air bubbles and produces a solid-like structure (Hartel 1996, Goff 1997).

Flavourings and colourings may be added either to the mix before freezing, or to the soft semi-frozen mix exiting the heat exchanger. The mix typically exits the barrel of the freezer at –6°C, and is transferred immediately to a hardening chamber (–30°C or below) where the majority of the unfrozen water freezes.

Today, ice cream is available in a wide range of forms and shapes (e.g., stick, brick or tub, low- or full-fat varieties).

PROTEIN HYDROLYSATES

The bovine caseins contain several peptide sequences with specific biological activities when released by enzymatic hydrolysis (Table 25.5). Such enzymatic hydrolysis can occur either *in vivo* during the digestion of ingested food, or *in vitro* by treating the parent protein with appropriate enzymes under closely controlled conditions.

Casein-derived bioactive peptides have been the subject of considerable research for several years and the very extensive literature has been reviewed by Miesel (1998), Pihlanto-Lappälä (2002), Gobbetti et al. (2002) and FitzGerald & Meisel (2003). Several bioactive peptides are liberated during the digestion of bovine milk, as shown by studies of the intestinal contents of consumers, confirming that such peptides are liberated *in vivo*.

Table 25.5. Range and Properties of Casein-Derived Peptides with Potential Biological Activity

Peptides	Putative Biological Activities
Phosphopeptides	Metal binding
Caseinomacropeptide	Anticancerogenic action; inhibition of viral and bacterial adhesion; bifidogenic action; immunomodulatory activity; suppression of gastric secretions
Casomorphins	Opioid agonist and ACE inhibitors (antihypertensive action)
Immunomodulating peptides	Immunomodulatory activity
Blood platelet-modifying (antithrombic) peptides (e.g., casoplatelin)	Inhibition of aggregation of platelets
Angiotensin converting enzyme (ACE)	Anti-hypertension action; blood pressure inhibitors (casokinins) regulation; effects on immune and nervous systems
Bacteriocidal peptides (casocidins)	Antibiotic-like activity

Laboratory-scale processes for the production and purification (e.g., using chromatography, salt fractionation or UF) of many interesting peptides from the caseins have been developed; enzymes used for hydrolysis include chymotrypsin and pepsin (Pihlanto-Lappälä 2002).

Bioactive peptides may also be produced on enzymatic hydrolysis of whey proteins; α- and β-lactorphins, derived from α-lactalbumin and β-lg, respectively, are opioid agonists and possess angiotensin-converting enzyme (ACE) inhibitory activity. The whey proteins are also the source of lactokinins, which are probably ACE inhibitory.

Currently, few milk-derived biologically active peptides are produced commercially. Perhaps the peptides most likely to be commercially viable in the short term are the caseinophosphopeptides, which contain clusters of phosphoserine residues and are claimed to promote the absorption of metals (Ca, Fe, Zn) through chelation, and acting as passive transport carriers for the metals across the distal small intestine, although evidence for this is equivocal (Miquel and Farré 2008, Phelan et al. 2009). Caseinophosphopeptides are currently used in some dietary and pharmaceutical supplements, for example in the prevention of dental caries.

The CMP (κ-CN f106–169) is a product of the hydrolysis of the Phe_{105}–Met_{106} bond of κ-casein by rennet; during cheesemaking, it diffuses into the whey, while the *N*-terminal portion of κ-casein remains with the cheese curd. CMP has several interesting biological properties; for example it has no aromatic amino acids and is thus suitable for individuals suffering from phenylketonuria; however, it lacks several essential amino acids.

It also inhibits viral and bacterial adhesion, acts as a bifidogenic factor, suppresses gastric secretions, modulates immune system responses and inhibits the binding of bacterial toxins (e.g., toxins produced by cholera and *E. coli*). Of particular interest from the viewpoint of the commercial exploitation of CMP, relatively high levels of this peptide are present in whey (∼4% of total casein, 15–20% of protein in cheese whey, an estimated 180 × 10^3 tonnes per annum are available globally in whey), and can be recovered therefrom quite easily.

Overall, detailed information is lacking regarding the physiological efficacy and mechanism of action of many milk protein-derived peptides, and possible adverse effects. Technological barriers also remain in terms of methods for industrial-scale production and purification of desired products.

CHOCOLATE

Milk powder is a key ingredient in many chocolate products, to which they contribute flavour and texture, for example through the role of milk fat in retarding the undesirable appearance of a white discolouration called chocolate bloom. The presence of milk powder (at levels up to 20% w/w) also influences processing characteristics of the molten chocolate during manufacture, for example flow properties. Certain characteristics of WMP that may be undesirable in other applications (e.g., high free fat content, low vacuole volume) are actually advantageous in chocolate. For this reason, roller-drying was often preferred to spray-drying for the production of milk powder for chocolate, although the latter process may be modified to yield powers with optimised properties for this application (Keogh et al. 2003). In addition, new approaches for tailoring powder functionality for chocolate, such as extrusion, have been described (Franke and Heinzelmann 2008).

INFANT FORMULAE

Today, a high proportion of infants in the developed world receive some or all of their nutritional requirements during the first year of life from prepared infant formulae, as opposed to breast milk. The raw material for such formulae is usually bovine milk or ingredients derived therefrom, but there are significant differences between the composition of bovine and human milk. This fact has led to the development of specialised processing strategies for transforming its composition to a product more nutritionally suitable for the human neonate. Today, most formulae are in fact prepared from isolated constituents of bovine milk (e.g., casein, whey proteins, lactose), blended with non-milk components. This, combined with the requirement for high hygienic standards and the absence of potentially harmful agents, makes the manufacture of infant formulae a highly specialised branch of the dairy processing industry, with almost pharmaceutical-grade quality control.

Most infant formulae are formulated by blending dairy proteins, vegetable (e.g., soya) proteins, lactose and other sugars, with vegetable oils and fats, minerals, vitamins, emulsifiers and micronutrients (O'Callaghan et al. 2011). The mixture of ingredients is then homogenised and heat treated to ensure microbiological safety. Subsequent processing steps differ in the case of dry or liquid formulae.

The dairy ingredients used are generally demineralised, as the mineral balance in bovine milk is very different from that of human milk (Burling 2002), and desired minerals are added back to the formula as required. Certain proteins (e.g., lactoferrin and α-lactalbumin) are present at higher levels in human than in bovine milk, and β-lg is absent from the former. There is interest in fortifying infant formulae with α-lactalbumin and/or lactoferrin, although technological challenges exist in the economical production of such proteins at acceptable purity.

The exact formulation of infant formulae differs based on the age and special requirements of the infant. Formulae for very young (<6-months old) babies generally have a high proportion of whey protein (e.g., 60% of total protein), whereas follow-on formulae for older infants contain a higher level of casein. In cases of infants with allergies to milk proteins or, in some cases, proteins in general, formulae in which milk proteins have been substituted by soya proteins or in which the proteins have been hydrolysed to small peptides and amino acids may be used. Soya-based formulae are also used in cases of intolerance to lactose.

The exact composition and level of added vitamins and minerals also differ based on nutritional requirements (O'Callaghan et al. 2011). Certain lipids are of interest as supplements for infant formulae, such as long-chain polyunsaturated fatty acids and conjugated linoleic acids. The final category of additives of interest for infant formulae is oligosaccharides, which are present at quite high levels (∼15 g/L) in human milk (Urashima et al. 2009). Such oligosaccharides may be produced enzymatically, chemically synthesised or produced by fermentations; for example conversion of lactose to prebiotic oligosaccharides by β-galactosidase, and challenges involved in such processes, were reviewed by Gosling et al. (2010).

Two main categories of infant formulae are available in most countries: dry and liquid (UHT). For dry powder manufacture, the liquid mix is concentrated by evaporation and spray-dried to yield a highly agglomerated powder that will disperse readily in warm water (dissolving infant formulae is probably the most common dairy powder reconstitution operation practiced by consumers in the home). Some components may be dry-blended with the base powder, allowing flexibility in manufacture for different applications (e.g., infant age, dietary requirements, etc.). Powdered formulae are typically packaged in N_2/CO_2-flushed cans.

Liquid formulae (ready-to-feed) are generally subjected to far more severe thermal treatment than those intended for drying, for example UHT processing followed by aseptic packaging or retort sterilisation of product in screw-capped glass jars. These products, which are stable at room temperature, have the obvious advantage of convenience over their dry counterparts.

NOVEL TECHNOLOGIES FOR PROCESSING MILK AND DAIRY PRODUCTS

In recent years, a number of novel processing techniques have been developed for applications in food processing; major

reasons for this trend include consumer demand for minimally processed food products, and ongoing challenges in satisfactorily processing certain food products without significant loss of quality using existing technologies (e.g., deterioration of nutrient content on heating fruit juices, problems with the safety of shellfish).

One new process that has received particular attention during the last decade is high pressure (HP) treatment. The principle of HP processing involves subjecting food products to a very high pressure (100–1000 MPa, or 1000–10,000 atm), typically at room temperature, for a fixed period (e.g., 1–30 minutes); under such conditions, microorganisms are killed, proteins denatured and enzymes either activated (at low pressures) or inactivated (at higher pressures). The principal advantage of HP processing, which does not rupture covalent bonds, is that low molecular weight substances, such as vitamins, are not affected and hence there are few detrimental effects on the nutritional or sensory characteristics of food.

Although it was first described for the inactivation of microorganisms in milk in the 1890s, by Bert Hite at the Agricultural Research Station in Morganstown, West Virginia, lack of available processing equipment meant that HP remained unexploited in the food industry for most of the twentieth century. Only in the late 1990s were HP-processed foods launched, such as shellfish in the United States, fruit juice in France and meat in Spain.

To date, no HP-processed dairy products are available, probably due, at least in part, to the complexity of the effects of HP on dairy systems, which necessitate considerable fundamental research to underpin future commercial applications.

In short, HP affects the properties of milk in several, often unique, ways (for reviews, see Huppertz et al. 2002, Trujillo et al. 2002). Key effects include the following:

- Denaturation of the whey proteins, α-lactalbumin (α-la) and β-lg, at pressures $\geq$200 or $\geq$600 MPa, respectively, and interactions of denatured β-lg with the casein micelles.
- Increased casein micelle size (by ∼25%) after treatment at 250 MPa for $\geq$15 minutes (Huppertz et al. 2004a) and reductions in micelle size by approximately 50% on treatment at 300–800 MPa.
- Increased levels of non-micellar $\alpha_{s1}-$, $\alpha_{s2}-$, β- and κ-caseins after HP treatment at $\geq$200 MPa.
- Inactivation of indigenous alkaline phosphatase and plasmin at pressures $\geq$400 MPa; lactoperoxidase is not inactivated by treatment at $\leq$700 MPa.
- Reduced rennet coagulation time of milk and time required for the gel to become firm enough for cutting, and enhanced strength of the rennet gel, following treatment at 200 MPa for up to 60 minutes or 400 MPa for $\leq$15 minutes.
- Increased yield of rennet-coagulated cheese curd, in particular after treatment $\geq$400 MPa.
- Increased rate and level of creaming in milk, by up to 70%, after HP treatment at 100–250 MPa, whereas treatment at 400 or 600 MPa reduces the rate and level of creaming by up to 60% (Huppertz et al. 2003).
- Reduced stability of milk to coagulation by ethanol (Johnston et al. 2002, Huppertz et al. 2004b),

HP treatment can also be applied to cheese (for review see O'Reilly et al. 2000a). A patent issued in Japan in 1992 suggested that the ripening of Cheddar cheese could be significantly accelerated by treatment at 50 MPa for 3 days; however, subsequent research (O'Reilly et al. 2001) has failed to substantiate this claim. There have been studies on the effects of HP on the ripening of many other cheese varieties; varying degrees of acceleration have been reported, for example Saldo et al. (2002) reported effects of HP treatment on ripening of cheese made from caprine milk. Of particular interest may be positive effects of HP treatment on the functionality of Mozzarella cheese (Johnston et al. 2002, O'Reilly et al. 2002a). HP may also be used to modify the microbial population (either starter or contaminants) in cheese (O'Reilly et al. 2000b, 2002b, Voigt et al. 2010).

In the last few years, the first commercial processes applying HP technology in the dairy sector have appeared, particularly for high-value functional foods (Kelly and Zeece 2009). Fonterra in New Zealand have proposed the commercial application of HP treatment for processing of bovine colostrum, with HP achieving a commercially relevant shelf life while retaining functional activity; to achieve a comparable shelf life using heat treatment would require heating of sufficient severity to result in loss of functionality of IgG through denaturation. In addition, Fonterra have patented a process whereby the shelf life of probiotic yoghurt may be extended by HP treatment to inactivate spoilage microorganisms while leaving active specially selected baro-resistant strains of probiotic bacteria, and a process for inactivating microorganisms in preparations containing lactoferrin.

Another technology that may be of potential interest for dairy processing in the future is high-pressure homogenisation (HPH), which works like conventional homogenisation, but at significantly higher pressures, up to 250 MPa; a related process, microfluidisation, is based on the principle of collisions between high-speed liquid jets. As well as reducing the size of oil droplets in an emulsion, HPH may inactivate enzymes and microorganisms and denature proteins in food. Many effects of HPH are due to the extremely high shear forces encountered by a fluid being processed; however, there is also a significant heating effect during the process. Recent studies have indicated that HPH significantly inactivates bacteria in raw bovine milk, and affects its rennet coagulation properties, fat globule size distribution and enzyme profile (Hayes and Kelly 2003a, b).

Another novel process that may be applied to dairy products is pulsed electric field treatment (which inactivates microorganisms but has relatively few other effects; Datta and Deeth 2002b). Some other processes, such as ultrasonication, irradiation, addition of antimicrobial peptides or enzymes and addition of carbon dioxide, have been studied for potential application to milk (Datta and Deeth 2002a). Arguably, HP processing is the most likely of the novel processes to be adopted by the dairy industry in the near future, due to the availability of equipment for commercial processing, but scale of available equipment combined with high cost will remain a significant hurdle (Patel et al. 2008).

CONCLUSION AND SUMMARY

Milk is a very complex raw material, with constituents and properties that are sensitive to applied stresses such as heat, changes in pH or concentration. Changes that can occur include inactivation of enzymes, mineral distribution and equilibria and denaturation of proteins. The extent of such changes and the consequences for the properties and stability of milk depend on the severity of the treatment.

In addition to the physicochemical changes that occur during processing, many dairy products involve complex enzymatic pathways, such as those involved in cheese ripening; exogenous enzymes may be added to milk to achieve a variety of end results. Milk may be fractionated by a range of complex technological processes to yield a broad portfolio of food ingredients.

In conclusion, the processing of milk represents perhaps one of the most complex fields in food science and technology and while many underpinning principles have been characterised, much research remains to be done in several areas.

Equid Milk: Chemistry, Biochemistry and Processing

T. Uniacke-Lowe and P.F. Fox

Abstract: The characteristics of equid milk of interest in human nutrition include a high concentration of polyunsaturated fatty acids, a low cholesterol content, high lactose and low protein levels, as well as high levels of vitamins A, B and C. Compared to bovine milk, the protein fraction of equid milk contains proportionally less

casein and more whey proteins. The low fat and unique fatty acid profile of both equine and asinine milk result in low atherogenic and thrombogenic indices. The high lactose content of equid milk gives good palatability and improves the intestinal absorption of calcium that is important for bone mineralisation in children. The renal load of equid milk, based on levels of protein and inorganic substances, is equal to that of human milk, a further indication of its suitability as an infant food. The concentration of lysozyme, lactoferrin and *n*-3 fatty acids is exceptionally high in equid milk, suggesting a potential anti-inflammatory effect. Equine and asinine milk can be used for their prebiotic and probiotic activity and as alternatives for infants and children with cow milk protein allergy and other food intolerances.

While the gross composition of equine and asinine milk has been reasonably well established and the caseins have been fractionated and well characterised, the presence of κ-casein remains a contentious issue and there is little or no information on the physicochemical properties of equid milk. The only significant product from equine milk is the fermented product, koumiss.

The composition of equid milk suggests a product with interesting nutritional characteristics with potential use in dietetics and therapeutics, especially in diets for the elderly, convalescent and newborns, but the lack of scientific research must be addressed to develop the potential of equine and asinine milk in the health and nutritional markets.

INTRODUCTION

Approximately one-third of all mammalian genera are herbivores, more than half of which belong to two orders, (1) the Perissodactyla (odd-toed ungulates (hoofed animals)) and (2) the Artiodactyla (even-toed ungulates) (Savage and Long 1986). The horse and donkey belong to the order Perissodactyla that has three families: (1) Equidae (nine species of horses, donkey and zebras), (2) Tapiridae (four species of tapirs) and (3) Rhinocerotidae (five species of rhinoceros). Uniquely among species, all Equidae can interbreed, but the hybrid offspring are almost always infertile because horses have 64 chromosomes and donkeys have 62 chromosomes (Trujillo et al. 1962). Zebras have between 32 and 46 chromosomes, depending on breed (Burchelli's zebra, *Equus burchelli*, has 44 chromosomes, Carbone et al. (2006) and viable hybrids with donkeys have been produced where gene combinations have allowed for embryonic development to birth. Differences in chromosome numbers between horses and zebras are most likely due to horses having two longer chromosomes that contain a single gene content compared to four zebra chromosomes (Benirschke et al. 1964).

This chapter presents a brief historical overview of some aspects of the domestication of equid species, a review of the chemistry and biochemistry of the principal constituents of equine milk and, to a lesser extent, of asinine milk, with comparative data for bovine and human milk. The technological properties of equid milk, with reference to processing of the milk are examined and, finally, a synopsis of the nutritional and biological significance of equid milks in the human diet is presented.

EQUID EVOLUTION

Perissodactyla species evolved during the early Eocene (∼55 million years ago) and were the dominant ungulate order until approximately 15 million years ago when numbers declined, probably due to climatic factors rather than competition with emerging Artiodactyla species (including the Ruminantia family) (MacDonald 2001). Nevertheless, wild equids ranged in vast herds across the grasslands of the Northern Hemisphere and in South America until the end of the ice age, approximately 10,000 years ago. Wild horses were the chief prey of increasing human populations and numbers decreased until they became extinct in North America approximately 7000 years ago and in Europe, herds of horses were pushed eastwards into Central Asia where the last few Przewalski horses (*Equus ferus przewalski*) survived until the twentieth century (Clutton-Brock 1992). It is generally assumed that equids were domesticated approximately 5000 years ago but archaeologists believe man did not ride horses until approximately 1000 BC, although horses replaced the ox as draft animals approximately 2000 BC (Clutton-Brock 1992). One of the early records of the domestic horse in Western Europe comes from horse remains found at the late Neolithic site at Newgrange, County Meath, Ireland (Clutton-Brock 1992). Outram (2009) demonstrated domestication of the horse in the Eneolithic Botai culture of Kazakhstan approximately 3500 years ago and analysis of organic residues based on characterisation of stable isotopes of carbon, $\delta^{13}C$ (which allows differentiation of non-ruminant and ruminant carcass and dairy fats) and deuterium δD, values of fatty acid analysis revealed processing of mares' milk and meat in ceramics at that time. The donkey (*Equus asinus*) is believed to have evolved from the Nubian and Somalian sub-species of African wild asses approximately 4000–5000 years ago and has since been an integral part of human life as a pack and riding animal. Today, perissodactyls are a poor second to artiodactyls in terms of numbers of species, geographical distribution, variety of form and ecological diversity (MacDonald 2001). For further details on equid evolution and genetic lineages of domestic horse species, see Vilà et al. (2001) and references therein.

EQUID DOMESTICATION

Only five major species of large, plant-eating mammals have been widely domesticated: sheep, goat, cattle, pig and horse. Nine additional minor species have been domesticated but are restricted to certain geographical areas: Arabian and Bactrian camels, llama, alpaca, donkey, reindeer, water buffalo, yak, Bali cattle of Southeast Asia and the gaur (mithan) of India and Burma (Bruns 1999). Despite taxonomic congruity and behavioural similarities between equid species, only two equids have been domesticated: the horse (*Equus ferus*) and the donkey (*Equus asinus africanus*) (Clutton-Brock 1992).

Because milk and products derived from it provide up to 30% of dietary protein in developed countries, to meet this demand, man has genetically improved some species for milk production (Mercier 1986). Domesticated animals have been modified from their wild ancestors through being kept and selectively bred for

use by humans who control the animals' breeding and feeding. Domestication of dairy species has meant that different breeds of farm animals, for example dairy cows and goats, can be developed and maintained to optimise certain hereditary factors, for example, length of lactation, period of gestation and milk yield, as well as protein and fat levels in the milk produced. Genetic selection of breeds of horse and donkey for milk production has not occurred, as yet, and consequently there is high variability for milk yield and length of lactation, as well as high individual variability.

In some regions of the world, for example Mongolia and Southern Russia, Hungary, France and Belgium, the horse and, less frequently, the donkey, is an important source of meat and milk. Steppe Mongols, forest-steppe Kazakhs, the Hadza hunter–gatherers of Tanzania and the urban French all regard horses as a valuable food source and believe that horse flesh and milk have special nutritional and medicinal attributes (Levine 1998). The use of donkeys as a dairy species can be traced back to Roman times when the nutritional value of its milk and beneficial properties in skin care were first recognised (Salimei 2011).

The importance of the horse in leisure activities, especially racing, has led to the scientific breeding and nutrition of horses, including foals, and has created the need to characterise the composition and properties of equine milk, which are now relatively well known. The fact that the horse is spread throughout the world, has been domesticated, is relatively easily handled, and produces large amounts of milk, which can be obtained relatively easily, makes equine milk a relatively easy subject for research. Although the donkey is now less widely distributed than the horse, its milk can be obtained readily. The zebra has not been domesticated and although it is widespread in the wild in Africa and in captivity elsewhere, apparently it is very difficult to obtain zebra milk, even from captive animals. Studies of the social behaviour of equids have shown that there are no intrinsic reasons why the zebra has never been domesticated but it is believed that the peoples of Africa may have had cultural rather than biological reasons not to use zebras as pack animals (Clutton-Brock 1992).

RUMINANTS AND NON-RUMINANTS

The horse and donkey are non-ruminant herbivores and digest portions of their feed first enzymatically in a foregut and then ferment it in a very large sacculated hind-gut. Limited digestion occurs in the equid stomach which liquefies incoming feed and secretes gastric acid and pepsin to initiate breakdown of feed components. The equid digestive system is designed to process small amounts of food frequently (Sneddon and Argenzio 1998). Equids rarely fast for more than 2–4 hours at a time and naturally forage for 16–18 hours/day. Horses in the wild roam widely, grazing both day and at night on immature, easily digested food and exhibit few digestive problems in comparison to domesticated horses (Sellnow 2006). Unlike ruminants, and in keeping with their status as prey animals, horses do not require periods of rest to stop and ruminate. Ruminants have very efficient digestive systems with microbial breakdown of fibrous food at the

start of the gastrointestinal tract and nutrient absorption along the entire intestine. Ruminants can digest fiber and carbohydrate more completely than any other species.

Donkeys, like horses, generally survive on a diet high in fiber and low in soluble carbohydrate and protein but while donkeys are not as efficient as ruminants at digesting cell wall components, they are far more efficient than horses (Izraely et al. 1989). Donkeys are capable of consuming large amounts of forage and gain more digestible energy from it than even goats fed a similar diet (Smith and Sherman 2009). The donkey achieves this by substantially increasing its forage intake rate to compensate for a low-quality diet. A donkey uses its narrower muzzle and prehensile lips for greater selectivity of its food, thereby, maximising feed quality rather than quantity (Aganga et al. 2000). Donkeys have a much lower water requirement per unit weight than any other mammal, except the camel, and can rehydrate quickly with large volumes of water without complications. Donkeys can work while suffering from severe dehydration by reducing water and energy turnover rates, while maintaining feed intake and its plasma volume can be maintained by drawing on the substantial fluid reservoir in the hind-gut (Sneddon et al. 2006). The zebra, on the other hand, needs a constant source of water for survival (Aganga et al. 2000).

WHY EQUID MILK IN HUMAN NUTRITION?

The benefits of equine milk for human health is an ancient idea and there is much literature from the former Soviet Union on this subject, although it is now accepted that the results of experimental work are dubious (Doreau and Martin-Rosset 2002). Because equine milk resembles human milk in many respects and is claimed to have special therapeutic properties, it is becoming increasingly important in Western Europe, especially in France, Italy, Hungary and the Netherlands. Equine milk (and koumiss, fermented equine milk) is often used for the treatment of a myriad of ailments including anaemia, nephritis, diarrhoea, gastritis disorders, cardiovascular disease and in post-operative care, as well as for stimulation of the immune system (Lozovich 1995). In Mongolia, where koumiss is the national drink, people have a saying that 'kumys cures 40 diseases' (Levine 1998). In Italy, equine milk has been recommended as a possible substitute for bovine milk for allergic children (Curadi et al. 2001). Equine milk is considered to be highly digestible, rich in essential nutrients and possesses an optimum whey protein:casein ratio, making it very suitable as a substitute for bovine milk in paediatric dietetics. Estimates suggest that more than 30 million people drink equine milk regularly, with this figure increasing significantly annually (Doreau and Martin-Rosset 2002).

The use of asinine milk by humans for alimentary and cosmetic purposes has been popular since Egyptian antiquity. Cleopatra is reputed to have bathed daily in asinine milk and kept a herd of 700 to fill her bath. Hippocrates (460–370 BC) was a strong advocate of the use of asinine milk as a medicine and used it to cure many ailments including, liver disease, oedema, nosebleed, poisoning and wounds. Today, asinine milk is consumed mainly in countries where donkeys were traditionally bred, Asia, Africa and Eastern Europe but more recently it has

been used successfully as a substitute for human milk in Western Europe (Vincenzetti et al. 2008) and is the milk of choice in Italy for children with severe immunoglobulin E (IgE)-mediated cows' milk allergy. (Businco et al. 2000).

PRODUCTION OF EQUID MILK

The production of equine milk and the factors that affect it have been the subject of several reviews, including Doreau and Boulot (1989), Doreau et al. (1990), Doreau (1994), Doreau and Martin-Rosset (2002) and Park et al. (2006) and, therefore, is considered only briefly here.

World milk production was approximately 695 million tonnes in 2009, of which 84% was bovine, 13% buffalo and 3% sheep, goat and other species (IDF 2009). Statistics for milk production from species other than cows and buffalo are not very reliable and are available only from countries where these milks are processed industrially although it is accepted that, while bovine milk production figures have changed little in recent years, the production of milk from buffalo, camels, horses and donkeys is increasing. In Europe, it is estimated that about 1–1.3 million litres of equine milk are currently produced per annum but in countries such as Mongolia the figure is considerably higher, probably approximately 9 million litres.

A decade ago, equine milk was produced only in isolated small holdings in parts of Eastern Europe and Mongolia, but now there are large-scale operations in France, Belgium, Germany, Austria and the Netherlands. Asinine milk is produced in large donkey farms in Italy, France, Spain, Belgium, Xinjiang and Shanxi provinces of China, Ethiopia and Pakistan (Salimei 2011).

For equine milk production, milking begins when the foal reaches approximately 8 weeks and is eating some hay and grass. The mare is separated from the foal by day and milked approximately five times at intervals of about 2.5 hours and produces 1–1.5 L of milk at each milking. At night, the foal feeds freely (van Laar, Orchid's Paardenmelkerij, the Netherlands, personal communication). Thus, milk production is very labour intensive and expensive, with the result that equine milk is priced as a delicacy, typically, €11/L. Milking schedules are similar for asinine milk, but the yield is lower than that of the horse, approximately 350–850 mL of milk per milking, depending on several factors including: foal and mare management, milking procedure, stage of lactation, body size and condition and feeding regime (Salimei 2011). Mastitis is rarely a problem with equids and occurs only if teat injury occurs during milking. Furthermore, equid species appear to be relatively resistant to brucellosis and tuberculosis, which is advantageous from a dairy farming point of view (Stoyanova et al. 1988).

COMPOSITION OF EQUID MILK

With the exception of the major domesticated dairy species and humans, information on milk composition is poor and of >4500 mammalian species in existence, milk compositional data are available for approximately 200 species, of which, data for only approximately 55 species appears to be reliable. The milk of all mammals contains the same principal components: water, salts, vitamins, fats, carbohydrate and proteins, but these constituents differ significantly both quantitatively and qualitatively between species (Table 26.1), although species from the same taxonomic order, for example equids, produce milk of similar composition (Table 26.1). Equid milk is similar in composition to human milk but considerably different from that of other dairy mammals, for example cow, buffalo, sheep, goat, camel, llama and yak (Table 26.1). Why equid milk is so similar in macro composition to that of human milk is unclear, especially as equids and humans are phylogenetically distantly related. Inter-species differences in milk composition reflect very divergent patterns of nutrient transfer to the young and presumably reflect adaptations in maternal rearing of offspring to physiological constraints and environmental conditions (Oftedal and Iverson 1995). In all situations, lactation must be effective in providing nourishment to the offspring without over-taxing maternal resources.

The protein content of milk varies considerably between species and reflects the growth rate of the young. Bernhart (1961) found a linear correlation between the percent of calories derived from protein and the logarithm of the days to double birth weight for 12 mammalian species. For humans, one of the slowest growing and slowest maturing species, it takes 120–180 days to double birth weigh and only 7% of calories come from protein. In contrast, carnivores can double their birth weigh in as little as 7 days and acquire >30% of their energy from protein. Equid species take between 30 and 60 days to double their birth weight and, like humans, have an exceptionally low level of protein in their milk (Table 26.1). The high metabolic needs of the foal are met through frequent feeding. Equid milks have a significantly lower energy value than human milk, owing to their low fat content (Table 26.1).

The fat content of milk across species shows large variation and ranges from approximately 0.6% for some breeds of donkey and less than 1% for rhinoceros to approximately 50% in the milk of some seals. High-fat milks are important for some species, for example desert mammals, when maternal water economy is important and energy needs to be transferred to the young in an efficient manner. Equid milk has one of the highest contents of carbohydrate, which is similar to that of human milk. In equid species, lactation lasts naturally for approximately 7 months.

FACTORS THAT AFFECT THE COMPOSITION OF EQUID MILK

Stage of Lactation

Within species, the stage of lactation is the most important determinant of milk composition and the difference between colostrum and mid-lactation milk shows the most significant difference but absolute values and the direction of change vary among species (Casey 1989). Shorty after parturition, the mammary gland produces colostrum that is richer in dry matter, proteins, fat, vitamins and minerals (except calcium and phosphorus) but poorer in lactose than mature milk. One of the major biological benefits of colostrum is the presence of Igs, IgA, IgM and IgG, and high levels of some enzymes, including

Table 26.1. Gross Composition of the Milk of Equid Species and Some Dairy Species, with Human and Other Selected Species Included for Comparison

Species	Total Solids	Protein	Casein: Whey Ratio	Fat	Lactose	Ash	Gross Energy (kJ.kg^{-1} or kJ.L^{-1})	Days to Double Birth Rate

Values are expressed as [a]g.kg^{-1} or [b]g.L^{-1} Milk.

catalase, lipase and proteinase. Figure 26.1 shows the affect of lactation on the main constituents of equine milk and indicates a very rapid transition from equine colostrum to mature equine milk, that is within the first 24 hours of lactation. The concentration of protein in equine milk is very high, >15 g/100 g milk, immediately post-partum, but decreases rapidly to <4 g/100 g milk after 24 hours of lactation and to less than 2 g/100 g milk after 4 weeks of lactation (Fig. 26.1A). The casein to whey protein ratio in equine colostrum is 0.2:1 immediately post-partum and this changes to approximately 1.1:1 within 1 week. The protein content of bovine milk decreases during the first 3 months of lactation, but increases subsequently (Walstra et al. 2006a). The concentration of lactose in equine more than doubles during the first 24 hours (Fig. 26.1C), and this is also observed for bovine milk (Walstra et al. 2006a). The concentration of lactose in equine milk subsequently increases steadily throughout fur-

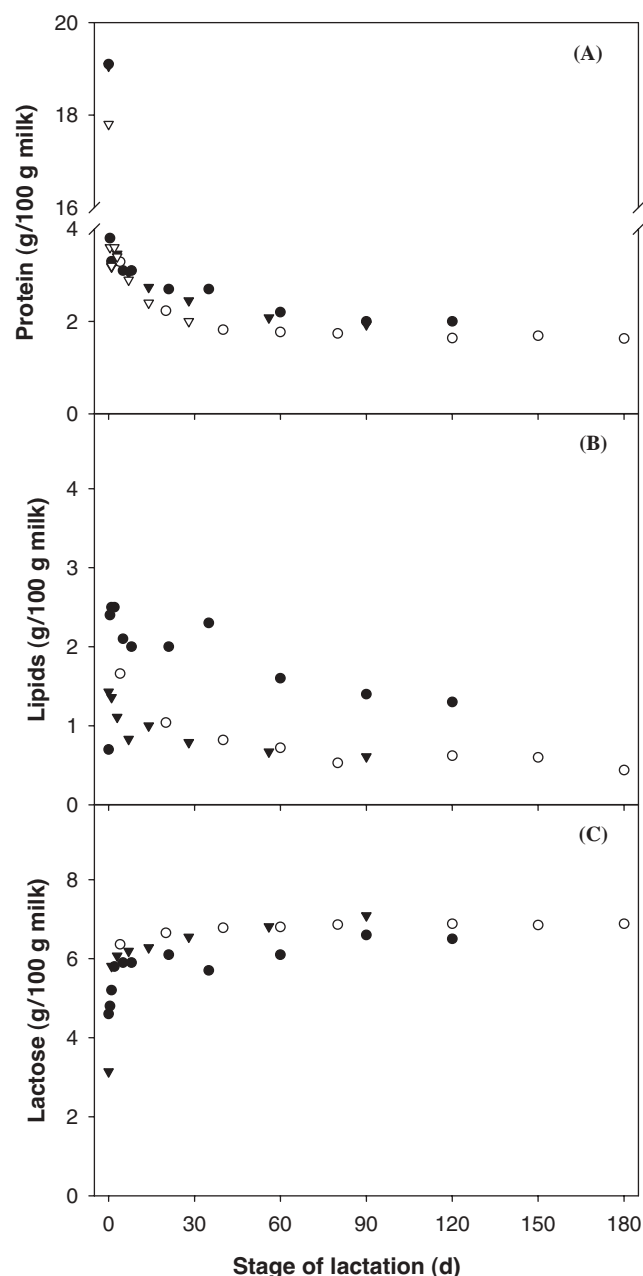
ther lactation (Fig. 26.1C), a trend that is different from that for bovine milk in which lactose content decreases progressively (Walstra et al. 2006a). Close agreement is observed between the data of various studies for the level of protein (Fig. 26.1A) and lactose (Fig. 26.1C) in equine milk but considerable differences are reported for the lipid content of equine milk between different studies (Csapó et al. 1995, Doreau et al. 1986). This may be due to an increase in the fat content of equine milk that occurs during a milking session and, in some cases, the use of the hormone, oxytocin, which promotes complete evacuation of the udder (Doreau et al. 1986). Hence, the volume of milk drawn and the degree of evacuation of the udder will significantly influence the lipid content of the milk and thus explain differences in lipid content observed between different studies. However, all studies indicated in Figure 26.1B show the same trend, that is a decrease in the lipid content of equine milk with


Figure 26.1. Influence of lactation stage on the concentration of (**A**) protein, (**B**) lipids, or (**C**) lactose in equine milk. (Data from Ullrey et al. (1966, ●), Mariani et al. (2001, ○) Smolders et al. (1990, ▼) and Zicker and Lönnerdal (1994, ▽).)

advancing lactation (Fig. 26.1B), whereas that the lipid content in bovine milk shows a distinct minimum after approximately 3 months of lactation (Walstra et al. 2006a). The fat content of asinine milk increases from approximately 0.5% to 1.5% from days 15 to 105 but decreases sharply thereafter (Guo et al. 2007, Salimei et al. 2004). Piccione et al. (2008) reported a decrease

in fat in the milk of Ragusana donkeys throughout lactation and observed a daily rhythmicity, similar to that found in bovine and human milk, for the levels of fat, lactose and protein in asinine milk, with fat and lactose peaking at night and protein reaching a maximum level during the daytime.

Effect of Equid Breed on Milk Composition

Data in the literature are not conclusive as to whether or not the breed of mare has an effect on the concentration of protein in milk. Kulisa (1977), Doreau et al. (1990), Csapó-Kiss et al. (1995) and Csapó et al. (1995) reported no effect of breed on the concentration of proteins or lipids in equine milk throughout lactation. On the other hand, Boulot (1987) and Formaggioni et al. (2003) have reported significant differences in protein content between breeds. Civardi et al. (2002), who compared Arabian, Haflinger, Trotter and Norico breeds, found that Norico milk had significantly lower α-lactalbumin (α-La), highest lysozyme (Lyz) and β-lactoglobulin (β-Lg) and highest thermal resistance of the breeds studied. Pelizzola et al. (2006), who compared the milk of Haflinger, Quarter horse, Sella/Salto and Rapid Heavy Draft, found that Quarter horse milk had significantly higher concentrations of the main constituents and higher concentrations of linoleic and α-linolenic fatty acids (ALA) than in the milk of the other species.

Asinine milk shows variability in fat content among breeds and is reported to be as low as 0.4% for Martina Franca mares, 0.6% in Ragusana mares and as high as 1.7% in Jiangyue donkeys (for these donkeys an increase from 0.5% to 1.7% was recorded in the fat content of the milk over 180 days of lactation) (Guo et al. 2007). Milk yield is significantly lower for Jiangyue donkeys than for Martina Franca and Ragusana breeds and the protein pattern of Jangyue milk is significantly different from the other breeds (Guo et al. 2007)

PROTEINS

While the protein content of mature equid milk is lower than that of bovine milk, there is a strong qualitative resemblance, the principal classes of proteins, that is caseins and whey proteins are similar in both milks. However, while the caseins are the predominant class of proteins in bovine milk (∼80% of total milk protein), equid milk contains less casein and more whey proteins. The distribution of casein and whey proteins in equid milk is shown in Table 26.2, with comparative data for bovine and human milk.

CASEINS

About 80% of the proteins in bovine milk are caseins that are primarily a source of amino acids, calcium, phosphate and bioactive peptides for neonates (Shekar et al. 2006). The low-casein concentration in mature equine milk (∼55% of total protein) has many implications that will be discussed later. The traditional method for separating caseins from whey proteins is isoelectric precipitation of the caseins at pH approximately 4.6. The casein fraction of most milks consists of four gene products: α_{s1}-,

Table 26.2. Concentration of Caseins and Whey Proteins (g. kg^{-1}) in Equine, Asinine, Human and Bovine Milk

	Equine	Asinine	Human	Bovine

NPN, non-protein nitrogen.

α_{s2}-, β- and κ-caseins, of which the first three are calcium sensitive. All caseins lack secondary structure, which led Holt and Sawyer (1993) to consider them as rheomorphic proteins. The lack of secondary structure may be attributed, at least partially, to the relatively high level of proline residues in casein. As a result, caseins do not denature or associate on heating (Paulson and Dejmek 1990). The biological function of the caseins lies in their ability to form macromolecular structures, casein micelles, which transfer large amounts of calcium to the neonate with a minimal risk of pathological calcification of the mammary gland. The individual caseins will be discussed separately in the following sections with focus on their interactions to form casein micelles and the colloidal stability thereof.

Fractionation and characterisation of individual equine caseins has been poorly researched to date in comparison to those of bovine milk and it had been reported that equine, and presumably asinine, caseins exhibit greater heterogeneity and a higher level of post-translational modifications than those of bovine milk (Miranda et al. 2004). Table 26.3 shows the biochemical properties of individual casein proteins that are discussed later.

Table 26.3. Properties of Equine, Bovine and Human α_{s1}-, β- and κ-Caseins

Protein	Species	Primary Accession Number[a]	Amino Acid Residues	Molecular Weight (Da)	pH	GRAVY[b]	Cysteine Residues

α_{S1}-Casein

The amino acid sequence of equine α_{s1}-casein has been deduced from its cDNA sequence (Lenasi et al. 2003). The protein contains 205 amino acids and has a molecular mass of 26,614.4 Da prior to post-translational modification, that is, it is considerably larger than its bovine or human counterpart (Table 26.3). Two smaller isoforms of α_{s1}-casein have been identified in equine milk, which probably result from the skipping of exons during transcription (Miranda et al. 2004). Equine α_{s1}-casein contains six potential phosphorylation sites (Lenasi et al. 2003), five of which are in very close proximity (Ser$_{75}$, Ser$_{77}$, Ser$_{79}$, Ser$_{80}$, Ser$_{81}$) and can thus form a phosphorylation centre, which is important in the structure of casein micelles. Matéos et al. (2009a) determined the different phosphorylation levels of the native isoforms of equine α_{s1}-casein and identified 36 different variants with several phosphate groups ranging from two to six or eight which, like equine β-casein, present a complex pattern on one dimensional and two dimensional electrophoresis. Bovine α_{s1}-casein contains eight or nine phosphorylation sites (Swaisgood 2003), which form two phosphorylation centres (De Kruif and Holt 2003). Bovine α_{s1}-casein contains three distinct hydrophobic regions, roughly including residues 1–44, 90–113 and 132–199 (Swaisgood 2003). These regions are characterised by positive values for hydropathy. Likewise, equine α_{s1}-casein has three domains with a high hydropathy value, that is, around residues 25–30, 95–105 and 150–205 and therefore it probably has association properties similar to those of bovine α_{s1}-casein. Furthermore, equine α_{s1}-casein contains two regions with very low hydropathy, that is, around residues 45–55 and 125–135, which are expected to behave hydrophilically. Human α_{s1}-casein does not appear to have distinct hydrophobic regions. Overall, equine and human α_{s1}-casein have comparable grand average hydropathy (GRAVY) scores, which are lower than that of bovine α_{s1}-casein (Table 26.3), indicating an overall higher hydrophobicity for the latter. GRAVY scores reflect the relative ratio of hydrophobic and hydrophilic amino acid residues in a protein, with a positive value reflecting an overall hydrophobic and a negative value an overall hydrophilic nature of the protein.

Prior to the mid-1990s, it was generally assumed that human milk contains mainly β- and κ-caseins with little or no α_s-casein (Kunz and Lönnerdal 1990). A minor casein component has since been identified and is considered to be the human equivalent of α_{s1}-casein, although this identification highlights several inconsistencies in comparison with the equivalent casein in other species. Uniquely, human α_{s1}-casein appears to contain at least two cysteine residues and exists as a multimer in complex with κ-casein (Cavaletto et al. 1994, Rasmussen et al. 1995). Johnsen et al. (1995) identified three cysteine residues in human α_{s1}-casein and provided a molecular explanation for α_{s1}-κ-casein complex formation. Martin et al. (1996) provided definitive evidence for the presence of a functional α_{s1}-casein locus in the human genome which is expressed in the mammary gland during lactation, while Sørensen et al. (2003) determined the phosphorylation pattern of human α_{s1}-casein. In bovine milk, α_{s1}- casein is a major structural component of the casein micelle and plays a functional role in curd formation

(Walstra and Jenness 1984). The relatively low level of α_{s1}-casein in equine milk (Table 26.2), and similarly in human milk, may be significant and, coupled with the low protein content, could be responsible for the soft curd produced in the stomach of the infant or foal (Dr. Ursula Fogarty, National Equine Centre, Ireland – personal communication). Goat milk lacking α_{s1}-casein has poor coagulation properties compared to milk containing α_{s1}-casein (Clark and Sherbon 2000). Bevilaçqua et al. (2001), who assessed the capacity of goat's milk with a low or high α_{s1}-casein content to induce milk protein sensitisation in guinea pigs, found significantly less sensitisation in milk with low α_{s1}-casein. This may represent another important attribute of the low α_{s1}-casein content of equine milk for use in human allergology.

An α_{s1}-like protein of approximately 31–33 kDa has been identified in asinine milk although Criscione et al. (2009) reported its absence in one Ragusana donkey under investigation.

α_{S2}-Casein

The complete amino acid sequence of equine α_{s2}-casein is unknown, but Ochirkhuyag et al. (2000) published the sequence of the N-terminal 15 amino acid residues (Lys-His-Lys-Met-Glu-His-Phe-Ala-Pro-Xaa-Tyr-Xaa-Gln-Val-Leu, where Xaa is an unknown amino acid). Only five of these amino acids were confirmed by Miranda et al. (2004). Isoelectric focusing showed two major bands for equine α_{s2}-casein, with isoelectric points in the pH range 4.3–5.1 (Ochirkhuyag et al. 2000). Bovine α_{s2}-casein is the most highly phosphorylated casein, usually containing 11 phosphorylated serine residues, with lesser amounts containing 10, 12 or 13 phosphate groups (Swaisgood 2003). There are no reports on the presence of α_{s2}-casein in human milk. Using three different methods for protein identification, Criscione et al. (2009) could not detect α_{s2}- or κ-casein in asinine milk.

β-Casein

The amino acid sequence of equine β-casein, derived from the cDNA, has been reported by Lenasi et al. (2003), and revised by Girardet et al. (2006) with the insertion of eight amino acids (glutamic acid (Glu$_{27}$) to Lys$_{34}$). The theoretical molecular mass of this 226 amino acid polypeptide is 25,511.4 Da (Table 26.3). Bovine and human β-casein contain 209 and 211 amino acid residues, respectively (Table 26.3). Two smaller variants of equine β-casein, which probably result from casual exon-skipping during transcription, were reported by Miranda et al. (2004). The 28 C-terminal amino acids contain seven potential phosphorylation sites (Ser$_9$, Ser$_{15}$, Ser$_{18}$, Ser$_{23}$, Ser$_{24}$, Ser$_{25}$, Ser$_{28}$) and multiple-phosphorylated isoforms of equine β-casein containing three to seven phosphoserine residues have been reported, with the isoelectric point varying from pH 4.74–5.30 (Girardet et al. 2006, Matéos et al. 2009b). Bovine β-casein, which contains four or five phosphorylated serine residues, has an isoelectric point of 5.0–5.5 (Swaisgood 2003). Human β-casein has up to six levels of phosphorylation, that is, 0, 1, 2, 3, 4 or 5 phosphorylated serine residues (Sood and Slattery 2000).

Equine, bovine and human β-casein have a very hydrophilic N-terminus, followed by a relatively random hydropathy distribution in the rest of the protein, leading to an amphiphilic protein with a hydrophilic N-terminus and a hydrophobic C-terminus. In equine sodium caseinate, the Lys_{47}–Ile_{48}, bond of β-casein is hydrolysed readily by bovine plasmin, whereas no cleavage of the corresponding bond, Lys_{48}–Ile_{49} in bovine β-casein has been shown (Egito et al. 2003). In bovine β-casein, Lys_{28}-Lys_{29} is readily cleaved by plasmin but the equivalent, Lys_{28}–Leu_{29}, in equine β-casein is insensitive (Egito et al. 2002). Other plasmin cleavage sites in equine β-casein are Lys_{103}–Arg_{104}, Arg_{104}–Lys_{105} and Lys_{105}–Val_{196} (Egito et al. 2002). Equine β-casein is readily hydrolysed by chymosin at Leu_{190}–Tyr_{191} (Egito et al. 2001).

Equine β-casein and equine α-La undergo spontaneous deamidation under physiological conditions at Asn_{135}–Gly_{136} and Asn_{45}–Gly_{46}, respectively (Girardet et al. 2004), which has been reported also for canine milk Lyz (Nonaka et al. 2008) and human lactoferrin (Lf) (Belizy et al. 2001) but not, to our knowledge, for bovine or human β-casein or α-la. Recent research has shown that temperature may be an important factor controlling the spontaneous deamidation process and at 10°C, the phenomenon is strongly reduced (Matéos et al. 2009b). Spontaneous deamidation represents an important modification of equine milk proteins under certain conditions where bovine milk proteins, which do not contain a potential site for deamidation, remain unaffected. Equine Lf also contains the Asn–Gly sequence and may be susceptible to spontaneous deamidation (Girardet et al. 2006).

Unique to equine milk and apparently absent from the milk of other species, including ruminants, is a low-molecular weight (MW) multi-phosphorylated β-casein variant which accounts for 4% of the total casein (Miclo et al. 2007). This short protein (94 amino acid residues) is the result of a large deletion (residues 50–181) from full-length equine β-casein. No spontaneous deamidation of this low-MW form of β-casein has been found. Multi-phosphorylated isoforms of β-casein, approximately 34–35.4 kDa, have been identified in asinine milk but no further characterisation has been reported to date (Criscione et al. 2009).

κ-Casein

The presence of κ-casein in equine milk was an issue of debate for several years, with several authors (Visser et al. 1982, Ono et al. 1989, Ochirkhuyag et al. 2000) reporting its absence. However, other studies (Kotts and Jenness 1976, Malacarne et al. 2000, Iametti et al. 2001, Egito et al. 2001) showed its presence, albeit at a low concentration. The primary structure of equine κ-casein has been derived (Iametti et al. 2001, Lenasi et al. 2003, Miranda et al. 2004); it contains 165 amino acids residues, that is four less than bovine κ-casein but three more than human κ-casein (Table 26.3). The MW of equine κ-casein, prior to post-translational modification, is 18,844.7 Da. Equine and human κ-casein have a considerably higher isoelectric pH than bovine κ-casein (Table 26.3), and they have a net positive charge at physiological pH, whereas bovine κ-casein has a net negative charge. The GRAVY score of bovine κ-casein is considerably lower than that of equine κ-casein (Table 26.3), indicating that the latter is more hydrophilic. Bovine κ-casein is characterised by a hydrophilic C-terminus, which is very important for the manner in which bovine casein micelles are stabilised, but a comparison of the hydropathy distribution of bovine and equine κ-caseins indicates that the C-terminus of equine κ-casein is far less hydrophilic, particularly as a result of the absence of a strong hydrophilic region at residues 110–120. Human κ-casein appears to be more like equine than bovine κ-casein in terms of the distribution of hydropathy along the polypeptide chain. Studies on asinine milk have not found κ-casein (Vincenzetti et al. 2008, Chianese et al. 2010).

Glycosylation of κ-Casein κ-Casein, the only glycosylated member of the casein family, exhibits microheterogeneity due to the level of glycosylation (Saito and Itoh 1992). Tri- or tetra-saccharides consisting of N-acetylneuraminic acid (NANA), galactose and N-acetylgalactosamine are attached to κ-casein *via O*-glycosidic linkages to threonine residues in the C-terminal portion of the molecule (the glycomacropeptide region). About two-thirds of bovine κ-casein molecules are glycosylated at one of six threonyl residues, that is Thr_{121}, Thr_{131}, Thr_{133}, Thr_{135}, Thr_{136} (only in bovine κ-casein variant A) or Thr_{142} (Pisano et al. 1994); Ser_{141} is also a potential glycosylation site (Kanamori et al. 1981). Human κ-casein has seven glycosylation sites, Thr_{113}, Thr_{123}, Thr_{128}, Thr_{131}, Thr_{137}, Thr_{147} and Thr_{149} (Fiat et al. 1980). Although no direct information is available, lectin-binding studies indicate that equine κ-casein is glycosylated (Iametti et al. 2001), possibly at residues Thr_{123}, Thr_{127}, Thr_{131}, Thr_{149} and Thr_{153} (Lenasi et al. 2003) (these glycosylation sites are not fully in agreement with those proposed by Egito et al. (2001)). To date, no non-glycosylated κ-casein has been identified in equine milk (Martuzzi and Doreau 2006).

κ-Casein is located mainly on the surface of the casein micelles and is responsible for their stability (Walstra 1990). The presence of a glycan moiety in the C-terminal region of κ-casein enhances its ability to stabilise the micelle, by electrostatic repulsion, and may increase the resistance by the protein to proteolytic enzymes and high temperatures (Minkiewicz et al. 1993, Dziuba and Minkiewicz 1996). Biologically, NANA residues have antibacterial properties and act as a bifidogenic factor (Dziuba and Minkiewicz 1996). κ-Casein is thought to play a major role in preventing the adhesion of *Helicobacter pylori* to human gastric mucosa (Strömqvist et al. 1995). It is likely that heavily glycosylated κ-casein provides some protection to breast-feeding infants due to its carbohydrate content which may be important especially as *H. pylori* infection is occurring at an increasingly younger age (Lönnerdal 2003).

Hydrolysis of κ-Casein   The hydrolysis of bovine κ-casein by chymosin at Phe_{105}–Met_{106} leads to the production of the hydrophobic N-terminal para-κ-casein and the hydrophilic C-terminal caseinomacropeptide (CMP) (Walstra and Jenness 1984). Chymosin hydrolyses the Phe_{97}–Ile_{98} bond of equine κ-casein (Egito et al. 2001) and slowly hydrolyses the Phe_{105}–Ile_{106} bond of human κ-casein (Plowman et al. 1999). However, as

Table 26.4. Properties of Equine, Bovine and Human Para-κ-Casein and Caseinomacropeptide

Protein	Species	Residues	Amino Acid Residues	Molecular Weight (Da)	pI	GRAVY[a]
Para-κ-casein	Equine	1–97	97	11,693.3	8.96	−0.675
	Bovine	1–105	105	12,285.0	9.33	−0.617
	Human	1–105	97	11,456.9	9.63	−1.004

	Human	106–162	65	6,723.7	4.24	0.182

[a]Grand average hydropathy (GRAVY) score using the scale of Kyte and Doolittle (1982).
Source: Modified from Uniacke et al. 2010.
CMP, *C*-terminal caseinomacropeptide.

summarised in Table 26.4, the CMPs released from equine and human κ-caseins are considerably less hydrophilic than bovine CMP. The sequence 97–116 of κ-casein is highly conserved across species, suggesting that the limited proteolysis of κ-casein and subsequent coagulation of milk are of major biological significance (Mercier et al. 1976, Martin et al. 2011)

A grouping system for mammals based on κ-casein structure and the site of cleavage by chymosin has been suggested (Mercier et al. 1976, Nakhasi et al. 1984). Group I species (cow, goat, sheep and buffalo) have a higher content of dicarboxylic amino acids and low hydrophobicity and carbohydrate content and κ-casein is cleaved at Phe_{105}–Met_{106}, while Group II species (horse, human, mouse, pig, rat) have a high proline content, less dicarboxylic amino acids and a much higher hydrophobicity and carbohydrate content and are cleaved at Phe_{97}–Ile_{98} or Phe_{105}–Leu_{106}. Marsupial κ-casein appears to form a separate group with a cleavage site different from that in eutherian mammals (Stasiuk et al. 2000). Cleavage of equine milk at Phe_{97}–Ile_{98}, as well as other characteristics of its κ-casein, place the horse in Group II. The divergence between species into Groups I and II could account for differences in the clotting mechanisms of ruminant and non-ruminant milks (Herskovits 1966). In addition to the differences in cleavage site, the grouping system also divides species based on the number of *O*-glycosylation sites in κ-caseins. As equine and human κ-casein are considerably more highly glycosylated than bovine κ-casein and non-glycosylated κ-casein has not been found in equine milk (Egito et al. 2001), equine and human κ-caseins belong to the same group. The level of glycosylation does not affect micelle structure but it does affect the susceptibility of κ-casein to hydrolysis by chymosin, with susceptibility decreasing as the level of glycosylation increases (Doi et al. 1979, Addeo et al. 1984, Van Hooydonk et al. 1984, Vreeman et al. 1986, Zbikowska et al. 1992). Therefore, equine milk probably has a different clotting mechanism by chymosin than bovine milk.

EQUID CASEIN MICELLES

In the milk of all species studied in sufficient detail, the caseins exist predominantly as micelles, which are hydrated spheri-

cal structures with dimensions in the sub-micron range. The dry matter of casein micelles consists predominantly (>90%) of proteins, with small amounts of inorganic matter, collectively referred to as micellar calcium phosphate (MCP). The structure and sub-structure of bovine casein micelles has been studied in detail and reviews include: Holt and Horne (1996), Horne (1998, 2006), De Kruif and Holt (2003), Phadungath (2005), Farrell et al. (2006), Qi (2007), Fox and Brodkorb (2008).

Equine casein micelles are larger than bovine or human micelles (Table 26.2) (Welsch et al. 1988, Buchheim et al. 1989) while those of asinine milk are similar in size to bovine micelles (Salimei 2011). Electron microscopy shows that bovine and equine micelles have a similar 'spongy' appearance, while human micelles seem to have a much 'looser', more open structure (Jasińska and Jaworska 1991). Such a loose open structure may affect the susceptibility to hydrolysis by pepsin. Jasińska and Jaworska (1991) reported that human micelles are much more susceptible to pepsin hydrolysis than either equine or bovine micelles. There are no specific reports on the sub-structure of equine casein micelles although equine milk does contain approximately 10.1 mmol.L^{-1} micellar calcium and approximately 2.6 mmol.L^{-1} micellar inorganic phosphate, suggesting a micellar calcium:casein ratio of >20:1 which, on a molar basis, far exceeds the calcium-binding capacity of equine casein molecules. Hence, it may be assumed that equine micelles, like bovine casein micelles, contain nanoclusters of calcium phosphate. Since equine milk contains little or no κ-casein, unphosphorylated β-casein may play a role in micellar stability (Ochirkhuyag et al. 2000, Doreau and Martin-Rosset 2002). A similar conclusion was reported by Dev et al. (1994) for the stabilisation of human casein micelles.

Both equine α_{s1}-casein (residues 75–81) and β-casein (residues 23–28) contain a phosphorylation centre, which is required for the formation of nanoclusters; furthermore, both proteins also contain distinct hydrophobic regions through which solvent-mediated protein–protein interactions may occur. Equine α_{s2}-casein may have similar properties to equine α_{s1}-casein, pending further characterisation. The ratio of micellar calcium:micellar inorganic phosphate is 2.0 in equine milk,

but approximately 3:9 in bovine milk (Holt and Jenness 1984) and might indicate that either a smaller proportion of micellar calcium is incorporated into nanoclusters in equine milk, or that equine nanoclusters contain a higher proportion of casein-bound phosphate, which would imply smaller nanoclusters. However, unlike bovine κ-casein, equine κ-casein does not have a distinctly hydrophilic C-terminal domain; thus, it is unclear if this part of the protein is capable of protruding from the micellar surface to sterically stabilise the micelles. Furthermore, given that the size of casein micelles and the content of κ-casein are inversely related (Yoshikawa et al. 1982, Dalgleish 1998.), a low level of κ-casein would be expected in equine milk compared to bovine milk. Further research is required to elucidate the structure of equine and asinine casein micelles as destabilisation of the micelles is the basis for the successful conversion of milk into a range of dairy products, for example cheese or yoghurt.

Stability of Equid Casein Micelles

Coagulation of milk occurs when the colloidal stability of the casein micelles is destroyed and may be desirable or undesirable. Coagulation is desirable in the manufacture of yoghurt and cheese and is also important from a nutritional point of view, as clotting of the caseins in the stomach, and the type and structure of the resultant coagulum strongly affect digestibility. In contrast, heat-induced coagulation of casein micelles, which can occur at a temperature $>120°C$, is undesirable. In this section, common types of micellar instability are described.

Bovine casein micelles are sterically stabilised by a brush of predominantly κ-casein (De Kruif and Zhulina 1996), which protrudes from the micelle surface. Coagulation of casein micelles can occur only following collapse of the brush, which occurs on acidification of milk, that is in the manufacture of yoghurt or on removal of the brush that occurs on rennet-induced coagulation of milk. The combined process of enzyme- and acid-induced coagulation is likely to contribute to coagulation of casein micelles in the stomach.

Enzymatic Coagulation of Equid Milk

Enzymatic coagulation of milk is the first step in the manufacture of most cheese varieties and also plays an important role in the flocculation of casein micelles in the stomach. For cheese manufacture, the process involves the addition of a milk-clotting enzyme, for example chymosin, to the milk, followed by incubation at a temperature $\geq 30°C$. During the incubation of bovine milk with rennet, chymosin hydrolyses the $Phe_{105}-Met_{106}$ bond of κ-casein, leading to the formation of two fragments, the hydrophobic N-terminal fragment, f1–105, which remains attached to the casein micelles and is referred to as para-κ-casein, and the hydrophilic C-terminal fragment, f106–169, which is released into the milk serum and is referred to as the CMP. As a result, the micelles lose steric stabilisation and become susceptible to aggregation, particularly in the presence of Ca^{2+} (for reviews, see Walstra and Jenness 1984, Wong et al. 1988, Walstra 1990, Fox and McSweeney 1998, Walstra et al. 2006b). Equine κ-casein is hydrolysed slowly by chymosin at the $Phe_{97}-Ile_{98}$ bond (Kotts and Jenness 1976, Egito et al. 2001), without gel formation, and it appears that either the chymosin-sensitive bond of equine κ-casein is located in the micelle in a manner that renders it inaccessible by chymosin, or that the equine casein micelle derives colloidal stability from constituents other than κ-casein. The high degree of glycosylation may also affect the ability of chymosin to hydrolyse equine κ-casein. Figure 26.2 illustrates the coagulation of equine, asinine and bovine milk by calf chymosin at 30°C. While it is clear that no gel is formed from equine milk, as judged by lack of an increase in storage modulus, G^1, asinine milk seems to form a gel, although it is very weak compared to the gel formed from bovine milk. Further investigation is warranted to determine if there are differences in the coagulation properties of asinine and equine milk.

Acid-induced Coagulation of Equid Milk

When bovine milk is acidified to a pH below 5.0, flocculation of casein micelles occurs, leading ultimately to gel formation. This process is the basis of the manufacture of yoghurt, in which acidification is induced by the production of lactic acid by lactic acid bacteria and also occurs at the low pH of the stomach (for
Figure 26.2. Rennet-induced coagulation of equine milk (----), asinine milk (---) and bovine milk (——) at 30°C.
Figure 26.3. Coagulation of equine milk (----), asinine milk (---) and bovine milk (——) acidified with 3% glucono-δ-lactone at 30°C.

review, see Lucey and Singh 2003). Acid-induced flocculation of bovine casein micelles is believed to result from a reduction in the solvency of the κ-casein brush on the micellar surface due to protonation of the negatively charged carboxylic acid groups of Glu and aspartic acid (Asp). Equine casein micelles are considerably less susceptible to acid-induced flocculation. Di Cagno et al. (2004) reported that equine milk acidified at pH 4.2, the point of minimum solubility of equine caseins (Egito et al. 2001), had an apparent viscosity only approximately seven times higher than that of equine milk at its natural pH (Waelchli et al. 1990) and is probably indicative of micellar flocculation rather than gelation. By comparison, the viscosity of acidified bovine milk is approximately 100 times higher than that of bovine milk at natural pH. Differences in acid-induced flocculation between equine and bovine casein micelles may be related to differences in the mechanism by which they are sterically stabilised. Figure 26.3 shows the effect of acidification of bovine, equine and asinine milk at 30°C and 3% glucono-δ-lactone (GDL). Asinine milk appears to form a weak gel when treated with GDL, unlike equine milk that shows little or no gel formation. Elucidation of the mechanism of steric stabilisation of equine casein micelles is likely to shed further light on this subject.

Heat-induced Coagulation of Equine Milk

Although milk, compared to most other foods, is extremely heat-stable, coagulation does occur when heated for a sufficiently long time at >120°C. Unconcentrated bovine milk, usually assayed at 140°C, displays a typical profile, with a heat coagulation time (HCT) maximum (~20 minutes) at pH approximately 6.7 and a minimum at pH approximately 6.9 (O'Connell and Fox 2003). In contrast, the HCT of unconcentrated equine milk at 140°C increases with pH, that is, it has an almost sigmoidal pH-HCT profile (Fig. 26.4), from <2 minutes at pH 6.3–6.9 to >20 minutes at pH 6.9–7.1; a slight maximum is observed at pH 7.2. Pre-heating unconcentrated milk shifts the pH-HCT profile and reduces the HCT in the pH region around the maximum, similar to the effect reported for bovine milk (O'Connell and Fox 2003). The HCT of concentrated equine milk at 120°C increases up to pH 7.1 but decreases progressively at higher pH values. While the profile for concentrated bovine milk is some-

what similar, the maximum HCT occurs at a considerably lower pH, that is, approximately 6.6. Differences in heat stability between equine and bovine milk may be related to differences in steric stabilisation of the micelles and, while heat-induced complexation of β-Lg with κ-casein greatly affects the heat stability of bovine milk (O'Connell and Fox 2003), it is unlikely to do so in equine milk due to lack of a sulphydryl group in equine β-Lg. The lower protein, particularly casein, concentration in equine milk is also likely to contribute to its higher heat stability.

The colloidal stability of equine casein micelles differs considerably from that of bovine casein micelles, which may have significant implications for the conversion of equine milk into dairy products. On the basis of the evidence outlined, manufacture of cheese and yoghurt from equine milk is unlikely to be successful using conventional manufacturing protocols.

Stability of Equine Milk to Ethanol

The ethanol stability of bovine milk (for review, see Horne 2003), defined as the minimum concentration of added aqueous ethanol that causes it to coagulate at its natural pH (~6.7), is 70–75% (added 1:1 to milk), whereas the ethanol stability of equine milk (pH ~7.2) is 40–45% (Uniacke-Lowe, 2011). The high concentration of ionic calcium and low level of κ-casein in equine milk probably contribute to its low ethanol stability.

WHEY PROTEINS

Similar to bovine milk, the major whey proteins in equine and asinine milk are β-Lg, α-La, Igs, blood serum albumin (BSA), Lf and Lyz (Bell et al. 1981a, Salimei et al. 2004, Guo et al. 2007). Except for β-Lg, all these proteins are also present in human milk. However, the relative amounts of the whey proteins differ considerably between these milks (Table 26.2). Compared to bovine milk, equine milk contains less β-Lg but more α-La and Igs. The principal anti-microbial agent in equine milk is Lyz and to a lesser extent Lf (which predominates in human milk (Table 26.2). Both Lf and Lyz are present at low levels in bovine milk, in which Igs form the main defense against
Figure 26.4. Heat coagulation time-pH profile of raw unconcentrated skimmed equine milk at 140°C (**-----**), preheated and unconcentrated milk (**____**) and concentrated milk at 120°C (**---**).

microbes (Malacarne et al. 2002). Together, Ig A, G, M, Lf and Lyz provide the neonate with immune and non-immune protection against infection (Baldi et al. 2005).

β-Lactoglobulin

β-Lg is the major whey protein in the milk of most ruminants and is also present in the milk of some monogastrics and marsupials, but is absent from the milk of humans, camels, lagomorphs and rodents. β-Lg is synthesised in the secretory epithelial cells of the mammary gland under the control of prolactin. Although several biological roles for β-Lg have been proposed, for example facilitator of vitamin A (retinol) uptake and an inhibitor, modifier or promoter of enzyme activity, conclusive evidence for a specific biological function of β-Lg is not available (Sawyer 2003, Creamer and Sawyer 2011). β-Lg of all species studied binds retinol; β-Lg of many species, but not equine or porcine, binds fatty acids also (Pérez et al. 1993). During digestion, milk lipids are hydrolysed by pre-gastric and pancreatic lipases, greatly increasing the amount of free fatty acids that could potentially bind to β-Lg, displacing any bound retinol, and implying that fatty acid metabolism, rather than retinol transport, is the more important function of β-Lg (Pérez and Calvo 1995). Bovine β-Lg is very resistant to peptic digestion and can cause allergenic reactions on consumption. Resistance to digestion is not consistent among species, with ovine β-Lg being far more digestible than bovine β-Lg (El-Zahar et al. 2005). The digestibility of equine β-Lg, which has, to our knowledge, not been studied, warrants research, particularly considering the potential applications of equine milk as a hypo-allergenic dairy product.

Two isoforms of equine β-Lg have been isolated, β-Lg I and II, which contain 162 and 163 amino acids, respectively. The extra amino acid in equine β-Lg II is a glycine residue inserted after position 116 of β-Lg I (Halliday et al. 1991). Asinine milk also has two forms of β-Lg, I and II (MW. 18.5 and 18.2 kDa, respectively); two variants of β-Lg I, that is, A and B, are known and four variants of β-Lg II, A, B, C and D (Cunsolo et al. 2007). Godovac-Zimmermann et al. (1985, 1988a,b) reported that β-Lg I from asinine milk has 162 amino acids, similar to equine β-Lg I (from which it differs by 5 amino acids). β-Lg II in both asinine and equine milks has 163 amino acids and shows substantial differences between both milks, with only six clusters of amino acid residues conserved (Godovac-Zimmermann et al. 1990). Criscione et al. (2009) reported the absence of β-Lg II from more than 23% of Ragusana donkeys in one study.

Bovine β-Lg occurs mainly as two genetic variants, A and B, both of which contain 162 amino acids and differ only at positions 63 (Asp in variant A, Gly in variant B) and 117 (valine (Val) in variant A, alanine (Ala) in variant B); a further 11, less common, genetic variants of bovine β-Lg have also been reported (Sawyer 2003). On the basis of its amino acid sequence, unmodified equine β-Lg I has a molecular mass of 18,500 Da and an isoelectric pH of 4.85, whereas equine β-Lg II, despite having one more amino acid, has a molecular mass of 18,262 Da (ExPASy ProtParam Tool 2009), and an isoelectric pH of 4.71 (Table 26.5). Bovine β-Lg A and B have a molecular mass of 18,367 and 18,281 Da, respectively, and an isoelectric pH of 4.76 and 4.83, respectively (Table 26.5). Using the hydropathy scale proposed by Kyte and Doolittle (1982), equine β-Lg I and II have a GRAVY score of

−0.386 and −0.300, respectively (Table 26.5). Bovine β-Lg A and B have a GRAVY score of −0.167 and −0.162, respectively (Table 26.5), and are, therefore, considered to be less hydrophilic than equine β-Lg I and II. Both equine and bovine β-Lg contain two intramolecular disulphide bridges, linking Cys_{66} to Cys_{160} and Cys_{106} to Cys_{119} in equine β-Lg I, Cys_{66} to Cys_{161} and Cys_{106} to Cys_{120} in equine β-Lg II and Cys_{66} to Cys_{160} and Cys_{106} to Cys_{119} or Cys_{121} in bovine β-Lg A and B. Bovine β-Lg contains one sulphydryl group at Cys_{119} or Cys_{121}. Equine β-Lg contains only four cysteine residues and lacks a sulphydryl group that has major implications for denaturation and aggregation of the protein (see later).

At physiological conditions (neutral pH and β-Lg concentration >50 μM), bovine β-Lg occurs predominantly in dimeric form and at its isoelectric point (pH 3.7–5.2) the dimers associate into octamers but below pH 3.4 and above pH 8.0 the protein dissociates into its monomeric form (Gottschalk et al. 2003). Equine and asinine β-Lg I exist in the monomeric form only (Godovac-Zimmermann et al. 1990).

α-Lactalbumin

α-La, a unique milk protein, is homologous with the well-characterised C-type Lyz. It is a calcium metalloprotein, in which the Ca^{2+} plays a crucial role in folding and structure and has a regulatory function in the synthesis of lactose (Larson 1979, Brew 2003, Neville 2009).

Similar to the α-La of asinine, bovine, caprine, ovine, camelid and human milk, equine α-La contains 123 amino acids (Brew 2003). Equine α-La occurs as three genetic variants, A, B

and C, which differ by only a few single amino acid replacements (Godovac-Zimmermann et al. 1987). Bovine α-La occurs as two, or possibly three, genetic variants (Bell et al. 1981b) and human α-La has two genetic variants, one of which has been identified only recently (Chowanadisai et al. 2005). The primary structure of equine, bovine and human α-La differ only by a few single amino acid replacements, and the proteins have similar properties (Table 26.5). Equine α-La A, B and C have an isoelectric point at pH 4.95, 4.95 and 5.11, respectively, whereas bovine and human α-La have isoelectric point at pH 4.80 and 4.70, respectively (Table 26.5). The GRAVY scores of equine and bovine α-La are comparable, whereas that of human α-La is distinctly higher (Table 26.5), indicating a lower hydrophobicity. The eight-cysteine residues of bovine and human α-La form four intramolecular disulphide bonds, linking Cys_6 to Cys_{120}, Cys_{28} to Cys_{111}, Cys_{61} to Cys_{77} and Cys_{73} to Cys_{93}. On the basis of the very high similarity between equine, bovine and human α-Las, as well as the α-La of other species, it is very likely that equine α-La also contains four intramolecular disulphide bridges, in the aforementioned positions. Equine, bovine or human α-La does not contain a sulphydryl group.

Three genetic variants of equine α-La have been reported but asinine milk has only one (123 amino acid residues, Mw approximately 14.2 kDa and four disulphide bonds), although some heterogeneity has been shown. Two isoforms, A and B, of asinine α-La (whose isoelectric points differ by 0.23 units) have been reported but subsequent analysis showed that the protein has only one form and misidentification in earlier work was probably due to differences in calcium binding by asinine α-La (Giuffrida et al. 1992). The primary structure of asinine α-La

has been determined and differs from those of equine and bovine proteins with 39 and 40 amino acid substitutions, respectively (Godovac-Zimmermann et al. 1987).

Immunoglobulins

The concentration of whey proteins is significantly elevated in the colostrum of all ruminants and equids as maternal Igs are passed from mother to neonate after birth when the small intestine is capable of absorbing intact proteins. After a few days, the gut 'closes' and further significant passage of proteins is prevented and within 2–3 days, the serum level of IgG in the neonate is similar to adult levels (Widdowson 1984). In contrast, *in utero* transfer of Igs occurs in humans and in some carnivores Igs are passed to the newborn both before and after birth. The milk of species that provide prenatal passive immunisation tends to have relatively small differences in protein content between colostrum and mature milk compared to species that depend on post-natal passage of maternal Igs. In the latter cases, of which all ungulates are typical, colostrum is rich in Igs and there are large quantitative differences in protein content between colostrum and mature milk (Langer 2009).

Three classes of Igs, which form part of a mammal's natural defense against infection, are commonly found in milk, IgIgG, IgA and IgM; IgG is often sub-divided into two sub-classes, IgG_1 and IgG_2 (Hurley 2003, Madureira et al. 2007). All monomeric Igs consist of a similar basic structure of four polypeptides, two heavy chains and two light chains, linked by disulphide bridges, yielding a sub-unit with a molecular mass of approximately 160 kDa. IgG consists of one sub-unit, while IgA and IgM consist of two or five sub-units, with a molecular mass of approximately 400 or approximately 1000 kDa, respectively. The relative proportions of the Igs in milk differ considerably between species (Table 26.2). IgG is the principal Ig in equine colostrum, but IgA is the principal form in equine milk. In bovine milk and colostrum, IgG is the principal immunoglobulin, while IgA is the predominant Ig in human colostrum and milk.

Lactoferrin

Lf is an iron-binding glycoprotein, comprising of a single polypeptide chain of MW approximately 78 kDa (Conneely 2001). Lf is structurally very similar to transferrin (Tf), a plasma iron transport protein, but has a much higher (∼300-fold) affinity for iron (Brock 1997). Lf is not unique to milk although it is especially abundant in colostrum, with small amounts in tears, saliva and mucus secretions and in the secondary granules of neutrophils. The expression of Lf in the bovine mammary gland is dependent on prolactin (Green and Pastewka 1978); its concentration is very high during early pregnancy and involution and is expressed predominantly in the ductal epithelium close to the teat (Molenaar et al. 1996). Human, equine, asinine and bovine milk contain 1.65 , 0.58 , 0.37 and 0.1 g Lf/kg, respectively (Table 26.2). The concentration of Lf in asinine milk, which comprises approximately 4% of total whey protein, is significantly lower than in equine milk (Table 26.2).

Shimazaki et al. (1994) purified Lf from equine milk and compared its iron-binding ability with that of human and bovine Lfs and with bovine Tf. The iron-binding capacity of equine Lf is similar to that of human Lf but higher than that of bovine Lf and Tf. Various biological functions have been attributed to Lf but the exact role of Lf in iron-binding in milk is unknown and there is no relationship between the concentrations of Lf and Tf and the concentration of iron in milk (human milk is very rich in Lf but low in iron) (Masson and Heremans 1971).

Lf is a bioactive protein with nutritional and health-promoting properties (Baldi et al. 2005). Bacterial growth is inhibited by its ability to sequester iron and also to permeabilise bacterial cell walls by binding to lipopolysaccharides through its *N*-terminus. Lf can inhibit viral infection by binding tightly to the envelope proteins of viruses and is also thought to stimulate the establishment of a beneficial microflora in the gastrointestinal tract (Baldi et al. 2005). Ellison and Giehl (1991) suggested that Lf and Lyz work synergistically to effectively eliminate Gram-negative bacteria; Lf binds oligosaccharides (OSs) in the outer bacterial membrane, thereby opening 'pores' for Lyz to hydrolyse glycosidic linkages in the interior of the peptidoglycan matrix. This synergistic process leads to inactivation of both Gram-negative, for example *E. coli* (Rainhard 1986) and Gram-positive bacteria, for example *Staphylococcus epidermidis* (Leitch and Willcox 1999) bacteria. Furthermore, a proteolytic digestion product of bovine and human Lf, lactoferricin, has bactericidal activity (Bellamy et al. 1992). Bovine and human Lf are reported to have antiviral activity and a role as a growth factor (Lönnerdal 2003). The specific biological function of equine Lf has not been studied, but is likely to be similar to that of bovine and human Lf.

Equine Lf contains 689 amino acid residues, which is similar to bovine Lf and two more than human Lf (Table 26.5). Compared to most other milk proteins, Lf has a high isoelectric point, that is, at pH 8.32, 8.67 or 8.47 for equine, bovine or human Lf (Table 26.5). As a result, the protein is positively charged at the pH of milk and may associate with negatively charged proteins *via* electrostatic interactions. GRAVY scores are comparable for equine, bovine and human Lf (Table 26.5). Equine and human Lf contain 17 and 16 intra-molecular disulphide bonds, respectively (Table 26.5). On the basis of structural similarities with human Lf, it has been assumed that bovine Lf contains 16 intra-molecular disulphide bonds (Table 26.5). The iron-binding capacity of equine, bovine and human Lfs are equivalent, although the pH-dependence of the iron-binding capacity of bovine Lf differs from that of equine and human Lf (Shimazaki et al. 1994).

All Lfs studied to date are glycosylated, but the location and number of potential glycosylation sites, as well as the number of sites actually glycosylated, vary. In bovine Lf, four out of five potential glycosylation sites, that is, Asn_{223}, Asn_{368}, Asn_{476} and Asn_{545}, are glycosylated (Moore et al. 1997), whereas in human Lf, two of three potential glycosylation sites, that is, Asn_{137} and Asn_{478}, are glycosylated (Haridas et al. 1995). Glycosylation of equine Lf has not been studied, but using the consensus sequence, Asn-Xaa-Ser/Thr (where Xaa is not Pro), for glycosylation, three potential glycosylation sites are likely in equine Lf, that is Asn_{137}, Asn_{281} and Asn_{476}.

Whey Protein Denaturation

Whey proteins are susceptible to heat-induced denaturation. The thermal stability of equine Lf and BSA is comparable to that of the bovine proteins but equine β-Lg and α-La are more heat stable than the bovine proteins (Bonomi et al. 1994). Equine β-Lg is more thermally stable than equine α-La, which is different from bovine milk, where α-La is the more thermally stable (Civardi et al. 2007). The high thermal stability of equine β-Lg may be related to its lack of a sulphydryl group. Thermal denaturation of bovine β-Lg is a two-stage process, unfolding of the polypeptide chain and exposure of the sulphydryl group, followed by self-association or interaction with other proteins *via* sulphydryl–disulphide interchange (Sawyer 2003). Owing to the lack of a sulphydryl group, equine β-Lg cannot undergo the second denaturation step and therefore its structure may refold on cooling. Denaturation of α-La is commonly a result of complex formation with β-Lg *via* sulphydryl–disulphide interchange and its higher thermal stability may therefore be a result of differences in its environment, rather than its molecular structure. Recent research suggests that equine α-La and β-Lg are also less susceptible to denaturation than their bovine counterparts under high pressure.

DIGESTIBILITY OF EQUID MILK

Milk is highly digestible and, because it is liquid, the gastrointestinal tract of mammals has mechanisms for delaying its passage; coagulation of milk in the stomach delays the degradation of proteins and improves their assimilation by the body. Caseins are precipitated by gastric acid and enzymes, forming a clot in the stomach that entraps fat. The hardness of this clot depends on the casein content of the milk; high casein-containing milks will produce firm clots. Generally, species that nurse their young at frequent intervals, for example equids and humans, tend to produce dilute milk in which <60% of total protein is casein and which form a soft clot, whereas those that nurse infrequently, for example cattle and sheep, produce milk that is high in fat and casein and has much longer gastric retention (Jenness 1986). Degradation of casein in the gastrointestinal tract is slow but extensive and while β-Lg is relatively resistant to gastric proteolysis, α-La is readily hydrolysed when the gastric pH is approximately 3.5 (Savalle et al. 1988).

The physico-chemical differences between human and bovine caseins result in the formation of different types of curd in the stomach (Hambræus 1982) and because the protein profile of equine milk is quite similar to that of human milk, equine milk may be more suitable in human nutrition than bovine milk. Turner (1945) compared the digestibility of equine, human and bovine milk based on the average percentage conversion of acid-insoluble protein to acid-soluble protein during digestion. Equine and human milk have a much lower buffering capacity than bovine milk and, while equine milk is very digestible, it is slightly less than human milk but significantly better than bovine milk. Turner (1945) concluded that both equine and human milk form soft curds in the stomach that pass through the digestive tract more quickly than bovine milk curd. Kalliala et al. (1951)

also reported that the overall digestibility of equine and human milk (by *in vitro* experiments) appeared to be quite similar and both were easier to digest than bovine milk. Human milk forms fine, soft flocs in the stomach with an evacuation time of 2–2.5 hours, whereas bovine milk forms compact hard curds with a digestion time of 3–5 hours.

TOTAL AMINO ACIDS

Guo et al. (2007) investigated the total amino acid composition of asinine milk and expressed the results both in grams of individual amino acids per 100 grams of milk and per 100 grams of protein and compared values to those for equine, bovine and human milk (Table 26.6). Results expressed per 100 g of milk demonstrated differences related, most likely, to differences in the total protein content between the milks, but when expressed as g/100 g protein, the differences were not so apparent. It has been reported that glycine is exceptionally high in equine casein (Lauer and Baker 1977) and other studies have reported that the mean values of peptide-bound amino acids in equid milks are generally higher than those in camel and buffalo milks and may indicate that equid milks are more suitable for human consumption than other milks studied to date. Asinine milk has noticeably higher levels of serine, glutamate, arginine and valine and much less cystine and the percentage of seven of the eight essential amino acids (isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tyrosine, valine) is also higher than those of equine and bovine milk (Guo et al. 2007). In equine, bovine and human milk cystine, glycine, serine, threonine and alanine decrease as lactation progresses while glutamate, methionine, isoleucine and lysine tend to increase (Davis et al. 1994).

NON-PROTEIN NITROGEN

The non-protein nitrogen (NPN) of milk consists primarily of urea, peptides, amino acids and ammonia. NPN constitutes 10–15% of the total nitrogen in mature equine milk which is intermediate between the values for human milk and ruminant milk, 25% and 5%, respectively (Hambræus 1984, Oftedal et al. 1983, Atkinson et al. 1989, Walstra et al. 2006b). In equine milk, NPN increases from <2% of total nitrogen at parturition to >10% after 2 weeks (Zicker and Lönnerdal 1994). The components of the NPN in human and bovine milk have been characterised (see Atkinson et al. 1989, Atkinson and Lönnerdal 1995, Rudloff and Kunz 1997, Carratù et al. 2003), but the NPN of equine milk has not been studied in detail.

Up to 50% of the NPN of human milk is urea and free amino acids, the exact function of which is, as yet, unknown. Asinine milk has a significantly higher level of NPN than equine milk and is close to that of human milk (Table 26.2). Equine and asinine milk have similar urea levels.

FREE AMINO ACIDS

The free amino acid content of equine, bovine and human milk are 1960, 578 and 3019 μmol.L^{-1}, respectively (Rassin et al. 1978, Agostini et al. 2000) (Table 26.7). Glutamine, glutamate,

Table 26.6. Amino Acid Composition of Asinine and Equine Milk
Expressed as g amino acid per 100 g Protein, with Comparative Data
for Bovine and Human Milk

[a]Rassin et al. 1978.
[b]Agostini et al. 2000.

glycine, alanine and serine are the most abundant free amino acids in equine, bovine and human milk, and taurine also is exceptionally high in human milk (Rassin et al. 1978, Sarwar et al. 1998, Carratù et al. 2003). Taurine is an essential metabolite for the human infant and may be involved in the structure and function of retinal photoreceptors (Agostini et al. 2000). Compared to bovine milk, equine milk has an appreciable amount of taurine although it is ten times less than that of human milk (Table 26.7). In contrast to total amino acid composition, which is essentially similar in equine, bovine and human milks, free amino acids show a pattern characteristic of each species (Table 26.7), which may be important for early post-natal development in different animals. Free amino acids are more easily absorbed than protein-derived amino acids and glutamic acid and glutamine, which comprise >50% of the total free amino acids of human milk, are a source of α-ketoglutaric acid for the citric acid cycle and also act as neurotransmitters in the brain (Levy 1998, Agostini et al. 2000).

BIOACTIVE PEPTIDES

Both caseins and whey proteins are believed to contribute to human health through latent biological activity produced enzymatically during digestion, fermentation with specific starter cultures or enzymatic hydrolysis by microorganisms, resulting in the formation of bioactive peptides. These peptides are important for their physiological roles, their opioid-like features, as well as their immunostimulating and anti-hypertensive activities and their ability to enhance Ca^{2+} absorption and are released or activated during gastrointestinal digestion. Several peptides generated by the hydrolysis of milk proteins are known to regulate the overall immune function of the neonate (Baldi et al. 2005). A detailed discussion on bioactive peptides in milk is outside the scope of this chapter, for reviews, see Donnet-Hughes et al. (2000), Shah (2000), Malkoski et al. (2001), Fitzgerald and Meisel (2003), Silva and Malcata (2005), Fitzgerald and Murray (2006), Lopéz-Fandiño et al. (2006), Michaelidou and Steijns (2006), Thomä-Worringer et al. (2006) and Phelan et al. (2009).

Research on the bioactive peptides derived from equid milk is very limited. Peptides from the hydrolysis of equine β-casein may have a positive action on human health (Doreau and Martin-Rosset 2002). Chen et al. (2010) reported the presence of four novel angiotensin-converting enzyme-inhibitory peptides in koumiss which may enhance the beneficial effects of koumiss on cardiovascular health. Peptides with trophic or protective activity have been identified in asinine milk (Salimei 2011).

HORMONES AND GROWTH FACTORS

Leptin is a protein hormone of approximately 16kDa that has been discovered recently in human milk and plays a key role in the regulation of energy intake and energy expenditure, as well as functioning in mammary cell proliferation, differentiation and apoptosis. Human-like leptin has been isolated from asinine milk at a level of 3.2–5.4 ng.mL^{-1} which is similar to

levels reported for other mammals and showed little variation throughout lactation (Salimei et al. 2002).

Levels of the bioactive peptides, ghrelin and insulin growth factor I, which play a direct role in metabolism, body composition and food intake, have also been reported for asinine milk at 4.5 pg.mL^{-1} and 11.5 ng.mL^{-1}, respectively, similar to levels in human milk (Salimei 2011).

AMYLOID A

Amyloid A3 (AA3) is a protein produced in the mammary gland and is encoded by a separate gene from that for serum amyloid A (serum AA) (Duggan et al. 2008). AA3 is believed to prevent attachment of pathogenic bacteria to the intestinal cell wall (Mack et al. 2003) and may prevent necrotising enterocolitis in human infants (Larson et al. 2003). McDonald et al. (2001) demonstrated the presence of AA3 in the colostrum of cows, ewes, sows and horses. Bovine colostrum has a high concentration of AA3 but by approximately 3 days *post-partum* the levels decline. In bovine milk, the presence of serum AA in milk is an indicator of mastitic infection (Kaneko et al. 2004, Winter et al. 2006). In equine colostrum, the concentration of AA3 is considerably lower than in milk and consequently may play a crucial role in intestinal cell protection in the foal especially after gut closure (Duggan et al. 2008).

INDIGENOUS ENZYMES

Milk contains many indigenous enzymes that originate from the mammal's blood plasma, leucocytes (somatic cells), or cytoplasm of the secretory cells and the milk fat globule membrane (MFGM)(Fox and Kelly 2006). The indigenous enzymes in bovine and human milks have been studied extensively but the enzymes in the milk of other species have been studied only sporadically. Equine milk probably contains all the enzymes that have been identified in bovine milk but relatively few studies have been reported.

LYSOZYME

Lyz (EC 3.1.2.17) occurs at high levels in equine, asinine and human milk (Table 26.2). Human, equine and asinine milk contain 3000, 6000 and >6000 times more Lyz, respectively, than bovine milk (Salimei et al. 2004, Guo et al. 2007) with levels as high as 0.4 g.100g^{-1} for Martina Franca donkeys (Coppola et al. 2002) although 0.1 g/100 g is reported and more commonly found in asinine milk (Vincenzetti et al. 2008). The concentration of Lyz in human milk increases strongly after the second month of lactation, suggesting that Lyz and Lf play major roles in fighting infection in breast-fed infants during late lactation, and protect the mammary gland (Montagne et al. 1998).

Equine milk Lyz is more stable to denaturation than human Lyz during pasteurisation at 62°C for 30 minutes but at 71°C for 2 minutes or 82°C for 15 seconds, the inactivation of both were similar (Jauregui-Adell 1975). It has been suggested, but research is scarce, that while the composition of breast milk varies

widely between well-nourished and poorly nourished mothers, the amount of Lyz is conserved.

Lyz found in egg white, tears and saliva do not generally bind calcium but equine and canine milk Lyz do and this is believed to enhance the stability and activity of the enzyme (Nitta et al. 1987). The binding of a Ca^{2+} by Lyz is considered to be an evolutionary linkage between non-Ca^{2+}-binding Lyzs and α-La (Tada et al. 2002, Chowdhury et al. 2004). The conformation of the calcium-binding loop of equine Lyz is similar to that of α-La (Tsuge et al. 1992, Tada et al. 2002) and both equine Lyz and α-La form stable, partially folded, 'molten globules' under various denaturing conditions (Koshiba et al. 2001,) with that of equine Lyz being considerably more stable than α-La (Lyster 1992, Morozova-Roche 2007). The molten state of canine Lyz is significantly more stable than that of equine Lyz (Koshiba et al. 2000, Spencer et al. 1999). Equine milk Lyz is very resistant to acid (Jauregui-Adell 1975) and proteolysis (Kuroki et al. 1989), and may reach the gut relatively intact.

Asinine Lyz contains 129 amino acids, is a C-type Lyz, binds calcium strongly and has 51% homology to human Lyz (Godovac-Zimmermann et al. 1988b). Two genetic variants of Lyz, A and B, have been reported in asinine milk (Herrouin et al. 2000) but only one is found in equine milk. Asinine Lyz is remarkably heat stable and requires 121°C for 10 minutes for inactivation. The Lyz content of equid milks is one of the main attractions for use of these milks in cosmetology as it is reputed to have a smoothing effect on the skin and may reduce scalp inflammation when incorporated into shampoo. Equid milk has very good antibacterial activity, presumably due to its high level of Lyz.

Other Indigenous Enzymes in Equine Milk

Lactoperoxidase, catalase, amylase, proteinase (plasmin), lipase, lactate dehydrogenase and malate dehydrogenase have been reported in equine milk. Bovine milk is a rich source of xanthine oxidoreductase (XOR) but the milk of other species for which data are available have much lower XOR activity, because in non-bovine species, most (up to 98% in human milk) of the enzyme molecules lack Mo and are inactive. XOR has not been reported in equine milk, which is unusual considering the role of XOR in the excretion of fat globules from the secretory cells and also considering that equine milk contains quite a high level of molybdenum (Mo), which presumably is present exclusively in XOR. Chilliard and Doreau (1985) characterised the lipoprotein lipase activity of equine milk and reported that the milk has high lipolytic activity, comparable to that in bovine milk and higher that in caprine milk. There are no reports on hydrolytic rancidity in equine milk, which is potentially a serious problem in equine milk products and warrants investigation.

Plasmin, a serine proteinases, is one of a number of proteolytic enzymes in milk. Visser et al. (1982) and Egito et al. (2002) reported γ-caseins in equine milk and, it is therefore assumed, that equine milk contains plasmin. Humbert et al. (2005) reported that equine milk contains five times more plasmin activity than bovine milk and 90% of total potential plasmin activity was plasmin, with 10% as plasminogen; the plasmin:plasminogen ratio in bovine and human milk is 18:82 and 28:72, respectively.

Alkaline phosphatase (ALP) is regarded as the most important indigenous enzyme of bovine milk because ALP activity is used as the index of the efficiency of high-temperature short-time pasteurisation. About 40% of ALP activity in bovine milk is associated with the MFGM. Equine milk has 35–350 times less ALP activity than bovine milk and there are no reports on ALP in the equine MFGM. Because of the low level of ALP in equine milk it has been suggested that it is not suitable as an indicator of pasteurisation efficiency of equine milk (Marchand et al. 2009) although one would expect that once the exact initial concentration of ALP is known, the use of a larger sample size or a longer incubation period would overcome the low level of enzyme.

CARBOHYDRATES

Lactose and Glucose

The chemistry, properties and applications of lactose are described in Chapter 24 and have been reviewed extensively elsewhere for example Fox (1985, 1997) and McSweeney and Fox (2009) and will not be considered here. The concentration of lactose in asinine milk is high (51–72.5 g.kg^{-1}), probably marginally higher than equine milk (approximately 64 g.kg^{-1}) (Table 26.2), which is similar to the level in human milk and significantly higher than that in bovine milk. As an energy source, lactose is far less metabolically complicated than lipids but the latter provides significantly more energy per unit mass. As well as being a major energy source for the neonate, lactose affects bone mineralisation during the first few months *post-partum* as it stimulates the intestinal absorption of calcium (Schaafsma 2003). Equine milk contains a significant concentration of glucose, approximately 50 mg/L in colostrum which increases to approximately 150 mg/L 10 days *post-partum* and then decreases gradually to approximately 120 mg/L (Enbergs et al. 1999). Although the lactose content of equid milks is high, the physico-chemical properties of lactose that cause problems in the processing of bovine milk are of no consequence for equid milks, which are consumed either fresh or fermented. In Mongolia, where approximately 88% of the population is lactose intolerant (Yongfa et al. 1984), lactose intolerance is not a problem with fermented equine milk, koumiss, as approximately 30% of lactose is converted to lactic acid, ethanol and carbon dioxide during fermentation.

Oligosaccharides

The milk of all species examined contains OSs but the concentration varies markedly (see Urashima et al. 2009). The OSs in milk contain 3 to 10 monosaccharides and may be linear or branched; they contain lactose at the reducing end and also contain fucose, galactosamine and *N*-acetylneuraminic acid. The highest levels are in the milk of monotremes, marsupials, marine mammals, humans, elephants and bears. OSs are the third most abundant constituent of human milk that has an exceptionally high content (approximately 20 g.L^{-1} in colostrum, which decreases to 5–10 g.L^{-1} in milk) and structural diversity of OSs ($>$200 molecular species), which have a range of functions,

Table 26.8. Principal Oligosaccharides of Equine Colostrum

Oligosaccharide	(mg/L)

including as important components of our immune system and as prebiotics to promote a healthy gut microflora (Donovan 2009). Bovine, ovine, caprine and equine milk contain relatively low levels of OSs, which have been characterised (see Urashima et al. 2001). The OSs identified in equine colostrum are summarised in Table 26.8. The OSs in mature equine milk have not been reported but it can be assumed that the level is considerably lower than in colostrum which has approximately 18.6 g/L (Nakamura et al. 2001). The neutral OSs, lacto-*N*-neotetraose and lacto-*N*-neohexaose, in equine colostrum are also abundant in human milk, while iso-lacto-*N*-neotetraose and lacto-*N*-novopentanose 1 are not, but have been identified in bovine colostrum; the latter has been identified also in the milk of the Tammar wallaby and brown capuchin monkey (Urashima et al. 2009).

LIPIDS

Milk fat is important for the provision of energy to the newborn as well as being the vehicle for fat-soluble vitamins and essential fatty acids. From a practical point of view, milk lipids are important as they confer distinctive nutritional, textural and organoleptic properties on dairy products. Dietary composition is considered one of the major determinants of the fatty acid composition of equid milk and non-dietary factors such as stage of lactation, age and parity of the mare play minor roles.

Triglycerides (TGs) represent approximately 80–85% of the lipids in equine and asinine milk, while approximately 9.5% are free fatty acids (FFAs) and approximately 5–10% are phospholipids (Jahreis et al. 1999). In contrast, approximately 97–98% of the lipids in bovine and human milk are TGs, with low levels of phospholipids and free fatty acids, 1.3 and 1.5 g.100g^{-1}, respectively. The high level of free fatty acids in equid milk implies that rancidity is a problem with these milks and is dealt with in Section 'Stability of Equine Milk Fat'.

The relatively high content of phospholipids in equid milk is thought to contribute to its buffering properties. TGs, the primary transport and storage form of lipids, are synthesised

in the mammary gland from fatty acids that originate from three sources: *de novo* synthesis (C8:0, C10:0 and C12:0), direct uptake from the blood (>14 carbons) and modification of fatty acids in the mammary gland by desaturation and/or elongation. Circulating fatty acids in the blood may originate from dietary fat or from lipids mobilised from body fat stores. The principal phospholipids of equid milk are phosphatidylcholine (19%), phosphatidylethanolamine (31%), phosphatidylserine (16%) and sphingomylin (34%); the corresponding values for bovine milk are 35%, 32%, 3% and 25% and for human milk are 28, 20, 8 and 39%, respectively. The high level of FFAs in equid milk implies considerable lipolysis but this has not been suggested; if lipolysis was responsible for the high level of FFAs, they should be accompanied by high levels of mono- and di-glycerides but these are reported to be quite low at approximately 1.8% of total lipids.

Table 26.9 shows the monounsaturated fatty acids (MUFA) and polyunsaturated fatty acids (PUFA) in the milk fat of some ruminant and non-ruminant species. The milk fat of non-ruminants contains substantially higher levels of PUFAs than ruminant milks due to the lack of biohydrogenation of fatty acids in the former, and for the two-equid species shown, the horse has considerably more PUFAs in its milk than the donkey. Saturated fatty acids are the dominant class in asinine milk and levels are significantly higher than those in equine or human milk (Table 26.9).

FATTY ACIDS IN EQUID MILKS

The fatty acid profile of equid milk (Table 26.10) differs from that of bovine and human milk fat in a number of respects. Like human, and unlike bovine milk, equid milk is characterised by low proportions of saturated fatty acids with low or higher numbers of carbons, that is, C$_{4:0}$, C$_{6:0}$, C$_{16:0}$ and C$_{18:0}$ (Pikul and Wójtowski 2008). Butyric acid (C$_{4:0}$) is present at high levels in bovine and other ruminant milk fats, produced from

Table 26.9. Monounsaturated and Polyunsaturated Fatty Acids (Percent of Total Fatty Acids ± Standard Deviations) in the Milk Fat of Some Ruminants and Non-Ruminants

	MUFAs	PUFAs	CLA
Non-ruminants			
Equine	20.70	36.80	0.09
Asinine	15.30	16.00	–
Porcine	51.80	12.40	0.23
Human	33.20	12.50	0.39
Ruminants			
Caprine	26.90	2.58	0.65
Bovine	23.20	2.42	1.01
Ovine	23.00	3.85	1.08

Data from Jahreis et al. 1999, Salimei et al. 2004.
MUFA, monounsaturated fatty acids; PUFA, polyunsaturated fatty acids; CLA, conjugated linoleic acid.

3-hydroxybutanoic acid, which is synthesised by bacteria in the rumen (Pikul and Wójtowski 2008). Caprylic acid, $C_{8:0}$, is very high in equid milk compared to the level in human and bovine milk (Table 26.10). Levels of middle chain-length FAs, especially $C_{10:0}$ and $C_{12:0}$, are high in equid milk (20–35% of all FAs contain <16 C) and in all non-ruminant herbivores, suggesting that they arise from the use of glucose as the principal precursor for fatty acid synthesis (Palmquist 2006). Mammalian *de novo* fatty acid synthesis requires a carbon source (acetyl-CoA) and reducing equivalents in the form of $NADPH + H^+$. In ruminants, acetate and β-hydroxybutyrate are the primary sources of carbon while glucose and acetate are the primary sources of reducing equivalents; in non-ruminants, for example equid species, glucose is the primary source of both carbon and reducing equivalents and also supplies some of the glycerol for milk TGs (Dils 1986). When horses were infused with either glucose or acetate and palmitate, $C_{12:0}$ and $C_{14:0}$ were formed exclusively from acetate, as in ruminants, and $C_{16:0}$ was formed, partly from acetate and partly from palmitate; unlike ruminants, 44% of $C_{18:0}$ and 7% of $C_{18:1}$ are formed from acetate in the horse (Palmquist 2006). If this is so, acetate and 3-hydroxybutyrate are presumably produced by bacterial fermentation in the lower intestine of the horse and why 3-hydroxybutyrate is not converted to butanoic acid, as in ruminants, is unclear. Fatty acids from $C_{6:0}$ to $C_{16:0}$ are released from the fatty acid synthesis complex by acyl-specific thioesterases; presumably, the middle chain-length-specific thioesterases are particularly active in equids; investigation of this possibility is warranted.

Equine milk-fat contains a relatively high level of $C_{16:1}$ (2–10%, w/w) and $C_{18:1}$, reflecting high Δ-9 desaturase activity. Equid milk fats contain a very high level of *n*-3-octadecatrienoic acid (linolenic acid), which reflects the high level of PUFAs in the diet and the lack of biohydrogenation, as occurs with ruminants. In the rumen, extensive hydrogenation of double bonds

occurs and most fatty acids taken up from the intestinal tract are saturated. The large intestine of equids shows significant differences in the relative rate of transport of volatile fatty acids compared to ruminants and *de novo* synthesis of $C_{18:0}$ fatty acids occurs with a further high proportion of $C_{6:0}$ to $C_{14:0}$ carbon fatty acids and some $C_{16:0}$ arising from products of their large bowel fermentation.

Equine and asinine milks have similar fatty acid profiles although the former has a higher content of monosaturated fatty acids (Tables 26.9 and 26.10). Both equine and asinine milk have characteristic low levels of stearic acid, and oleic acid is exceptionally low in asinine milk. Asinine and zebra milk fat contain a high level of PUFAs, although considerably lower than in equine milk. The well-balanced ratio of *n*-6: *n*-3 of 1.17:1 in asinine milk compared to 3.14:1 in equine milk makes it an interesting product for human nutrition. *n*-6 and *n*-3 fatty acids are essential in human metabolism as components of membrane phospholipids, precursors of eicosanoids, ligands for membrane receptors and transcription factors that regulate gene expression. The importance of *n*-6 $C_{18:2}$, linoleic acid (LA), has been known for many years but the significance of *n*-3 $C_{18:3}$, α-linolenic (ALA) was not recognised until the late 1980s and has since been identified as a key component in the diet for the prevention of atopic dermatitis (Horrobin 2000). LA and ALA are not inter-convertible but are the parent acids of the *n*-6 and *n*-3 series of long chain (LC) polyunsaturated fatty acids, respectively (e.g., *n*-6 $C_{20:4}$, arachidonic acid (AA); *n*-3 $C_{20:5}$, eicosapentaenoic acid (EPA) and *n*-3 $C_{22:6}$, docosahexaenoic acid (DHA)) which are components of cellular membranes and precursors of other essential metabolites such as prostaglandins and prostacyclins (Cuthbertson 1999, Innis 2007). DHA and AA are now recognised as being crucial for normal neurological development (Carlson 2001). Humans have evolved on a diet with a ratio of *n*-6 to *n*-3 fatty acids of approximately 1:1 but Western diets nowadays have a ratio of 15:1 to

Table 26.10. Typical Fatty Acid (Percent of Total Fatty Acids) Composition in the Milk of Equid Species; Bovine and Human Milk are Included for Comparison

16.7:1. As a species, humans are generally deficient in *n*-3 fatty acids and have excessive levels of *n*-6 which is associated with the pathogenesis of cardiovascular, cancerous, inflammatory and autoimmune diseases (Simopoulos 2002).

Equine milk-fat contains a very low level of conjugated linoleic acid (CLA; rumenic acid, Tables 26.9 and 26.10) which is virtually absent from asinine milk but is high in ruminant milk-fats, being produced in the rumen by abortive biohydrogenation of *n*-6 octadecadienoic acid (LA) (see Whigham et al. 2000, Bauman and Lock 2006, Collomb et al. 2006). CLA has several desirable effects in the diet; some of the positive health effects attributed to it include: suppression of carcinogenesis, anti-obesity agent, modulator of the immune system and control of artherogenesis and diabetes. Small amounts of eicosapentaenoic (EPA) and docosahexaenoic acid (DHA) are present in asinine milk whereas equine milk has only trace amounts. EPA and DHA are especially important in infant nutrition but their absence from equine milk is not considered to be a problem as an infant's liver can desaturate linoleic and ALA to form EPA and DHA.

STRUCTURE OF TRIGLYCERIDES

The distribution of fatty acids in animal TGs is non-random, apparently so that the TGs will be liquid at body temperature. Inter-species comparison of the positional distribution of fatty acids has been determined, using fatty acid and stereospecific analysis, for 11 species: echidna, koala, Tammar wallaby, guinea pig, dog, cat, Weddell seal, horse, pig, cow and human

(Parodi 1982). Generally, the positional distribution of fatty acids is similar, except for the echidna, with short chain fatty acids preferentially esterified at *sn*-3, saturated fatty acids at *sn*-1 and unsaturated fatty acids generally at *sn*-2. In equine milk fat, $C_{10:0}$ occurs at the *sn*-3 position, whereas in bovine milk fat, more $C_{10:0}$ is found at the *sn*-2 than at the *sn*-3 position. In human and equine milk, $C_{16:0}$ is located predominantly at the *sn*-2 position which is regarded as favourable for assimilation by infants and children, whereas in bovine milk, $C_{16:0}$ is equally distributed between the *sn*-1 and *sn*-2 positions. In the milk fat of the Weddell seal and horse, $C_{18:1}$ is esterified preferentially at *sn*-1 but for all other species studied it occurs mainly at *sn*-3 (Parodi 1982). No information is available on the stereospecific distribution of fatty acids in the TGs of asinine milk.

EQUID MILK FAT GLOBULES AND MFGM

The fat in milk is emulsified as globules which are surrounded and stabilised by a very complex emulsifying layer, consisting of phospholipids and proteins, called the MFGM. Many of the indigenous enzymes in milk are concentrated in the MFGM. The glycoproteins in the MFGM of human, rhesus monkey, chimpanzee, dog, sheep, goat, cow, grey seal, camel, horse and alpaca have been studied; large intra- and inter-species differences have been found (see Keenan and Mather 2006). Very highly glycosylated proteins occur in the MFGM of primates, horse, donkey, camel and dog. Long (0.5–1 μm) filamentous structures, comprising of mucins (highly glycosylated proteins),

extend from the surface of the fat globules in equine and human milk (Welsch et al. 1988). These filaments dissociate from the surface into the milk serum on cooling and are lost on heating. For unknown reasons, the filaments on bovine milk fat globules are lost much more easily than those in equine or human milk. The filaments facilitate the adherence of fat globules to the intestinal epithelium and probably improve the digestion of fat (Welsch et al. 1988). The mucins prevent bacterial adhesion and may protect mammary tissue against tumors (Patton 1999). The milk fat globules (MFGs) of asinine milk can be up to approximately 10 μm in diameter, whereas those of equine milk are generally smaller at 2–3 μm on average; the MFGs of bovine and human milk are 3–3.5 μm and approximately 4 μm, respectively. Little is known about the proteins of the MFGM of equids but they are known to play a major role in neonatal defense mechanisms in humans (see Mather 2000).

Butyrophilin, acidophilin and XOR have been identified in the equine MFGM and appear to be similar to the corresponding proteins of the human MFGM, as does lactadherin which shares 74% identity with that of the human lactadherin (Barello et al. 2008). Both XOR and acidophilin are involved in fat globule secretion with butyrophylin while lactadherin is thought to have a protective function against rotovirus in the intestinal tract (Barello et al. 2008). Like ovine and buffalo milk, equine milk does not cream due to the lack of cryoglobulin.

Rheology Equid Milk Fat

The temperature-dependent melting characteristics of bovine milk-fat have been studied thoroughly but since equid milk is not used for the production of butter, the spreadability, rheology and melting characteristics of these fats have not been studied in detail (see Chandan et al. 1971). Considering the rather unusual fatty acid profile of equid milk fats, they should have interesting melting and rheological properties.

Stability of Equine Milk Fat

Lipids generally are susceptible to two forms of chemical spoilage, lipid oxidation (oxidative rancidity) and lipolysis (hydrolytic rancidity) which are of great commercial significance to the dairy industry and have been studied in detail (see Fox and McSweeney 2006). No studies on the chemical spoilage of equid milk-fat have been reported. Considering the high content of PUFAs in these fats, they are probably quite susceptible to oxidation. Since equine milk contains a lipase, hydrolytic rancidity would be expected under certain conditions.

VITAMINS

The overall vitamin content of any milk depends on maternal vitamin status but water-soluble vitamins are more responsive to the maternal diet than fat-soluble vitamins. Vitamin levels in the milk of some species are shown in Table 26.11. The level of vitamin E is low in asinine milk ($\sim$0.05 mg.L^{-1}) and is reduced further if the milk is heated. Concentrations of fat-soluble vitamins are generally similar in equine and bovine milks (Table 26.12). The levels of vitamins A, D$_3$, K and C are significantly higher in equine colostrum than in equine milk, whereas the concentration

of vitamin E remains unchanged throughout lactation (Table 26.12)(Csapó et al. 1995).

MINERALS

MACRO-ELEMENTS

The levels of ash in equine and asinine milk are similar (Table 26.2) and the levels of inorganic elements are close to those in human milk except for higher concentrations of Ca and P (Table 26.13) (Holt and Jenness 1984). The principal salts in equine milk are phosphates, chlorides, carbonates and citrates of potassium, sodium, calcium and magnesium. However, there are considerable quantitative inter-species differences in milk salts, (Table 26.13). The concentrations of all macro-elements, except potassium, are higher in equine and asinine milk than in human milk but all are considerably lower than in bovine, caprine, ovine or porcine milk. The low level of salts in equid milk reduces renal load, making it suitable in infant nutrition. Pieszka and Kulisa (2005) reported on the low tolerance of equine species to imbalances in mineral concentrations in milk post-partum; slight increases in some minerals can cause severe deformation of teeth and bones in horses and affect metabolism and protein synthesis.

The concentration of macro-elements in equine milk is comparable to that in zebra milk (*Equus zebra*), whereas in early lactation, the concentrations of calcium and phosphate are considerably higher in domestic horse milk (*Equus caballus*)(Table 26.14) than in zebra milk (Schryver et al. 1986). The concentrations of macro-elements in equine milk are strongly influenced

by the stage of lactation (Fig. 26.5), which shows a progressive decrease in the concentrations of calcium, magnesium, phosphorus, sodium and potassium from the end of the first week of lactation. The concentration of calcium in equine milk increases during the first week of lactation, before decreasing steadily thereafter (Ullrey et al. 1966). As in the milk from all mammals which have been studied in sufficient detail, the concentrations of calcium and phosphate in equine milk far exceeds the solubility of calcium phosphate in milk. As a result, part of the calcium and phosphate exist in a non-ultrafiltrable, micellar, form, that is MCP. Holt and Jenness (1984) reported that approximately 60%, 20% or 40% of total calcium, magnesium or inorganic phosphorus, respectively, in equine milk are non-ultrafiltrable, compared to approximately 70%, 35% or 45% of total calcium, magnesium and inorganic phosphorus in bovine milk. On the basis of measurements of the distribution of salts between the ultrafiltrable and non-ultrafiltrable phase of milk, Holt and Jenness (1984) estimated the concentrations of ionic calcium and magnesium in equine milk at pH 7.0 are 2.5 and 0.6 mmol L^{-1}, respectively, compared to 2.0 or 0.8 mmol L^{-1}, respectively, in bovine milk at pH 6.7. For human infant nutrition, a Ca:P ratio of approximately 2:1 is considered optimal; for bovine milk, the ratio is approximately 1:1, but in equine milk it is about 2:1, and is very close to that in human milk.

Trace Elements

Data on concentrations of trace elements, that is, those elements present at concentrations less than 30 mg L^{-1}, in equine milk have been sporadic. The concentrations of trace elements in equine, bovine and human milk are compared in Table 26.15. Compared to bovine milk, equine milk contains markedly higher levels of aluminum, copper, iron and titanium but lower levels of boron, barium, lithium, molybdenum, manganese, silicon and zinc. Human milk contains more boron, barium, copper, iron, silicon and zinc, but less lithium, manganese, strontium and titanium than equine milk (Table 26.15). Concentrations of zinc, iron and copper in equine milk decrease progressively with advancing lactation, whereas the concentration of manganese increases during the first 5 days of lactation, after which it decreases progressively (Csapó-Kiss et al. 1995, Ullrey et al. 1974).

PHYSICAL PROPERTIES OF EQUID MILK

The physical properties of the milk of some species are compared in Table 26.16.

Density

The density (kg m^{-3}) of equine colostrum is higher than that of equine milk (Waelchli et al. 1990, Ullrey et al. 1966, Mariani et al. 2001), due primarily to its considerably higher protein content. Values for colostrum can reach up to approximately 1080 kg m^{-3} (Ullrey et al. 1966) and show a significant linear correlation with the IgG content of colostrum (Waelchli et al. 1990, LeBlanc et al. 1986). Density is highest immediately *postpartum* and decreases rapidly during the first 12 h (Ullrey et al. 1966); considerably smaller decreases in density are observed during the rest of lactation (Ullrey et al. 1966, Mariani et al. 2001). Density values reported for mature equine milk range from approximately 1028 to 1035 kg m^{-3}. The density of whole mature bovine milk normally ranges from 1027 to 1033 kg m^{-3} (Singh et al. 1997).

Refractive Index

The refractive index for equine colostrum ranges from 1.340 to 1.354, whereas that of mature equine milk is approximately

Table 26.16. Physical Properties of the Milk of Equid Species, with Comparative Data for Bovine and Human Milk

Property	Equine Milk	Equine Colostrum	Asinine Milk	Bovine Milk	Human milk
Freezing point (°C)	−0.525 – −0.554	–	−0.55 – −0.49	−0.512 – −0.55	–
pH (25°C)	7.1–7.3	–	7.01–7.35	6.5–6.7	6.8
Density (kg.m^{-3}), (20°C)	1032	1080	1029–1037	1027–1033	1031
Refractive index, $n_D{}^{20}$	1.3394	1.340–1.354	–	1.344–1.349	–
Viscosity (mPa s)	1.5031	–	–	1.6314	–
Zeta potential (mV)	−10.3	–	–	−20.0	–
Colour L*a*b*	86.52, −2.34, −0.15	–	80.88 −2.27 −3.53	79.12, −7.46 −2.31	–

Source: Modified from Uniacke and Fox 2011.

1.339 (Waelchli et al. 1990). The higher refractive index of colostrum than of mature milk is probably related to its higher total solids content, since the refractive index increases with increasing mass fraction of each solute. The refractive index of bovine milk is in the range 1.344–1.349 (Singh et al. 1997).

pH

There is considerable variation among reported values for the pH of equine milk. Mariani et al. (2001) reported that its pH 4 days *post-partum* is approximately 6.6 and increases to approximately 6.9 after 20 days and to approximately 7.1 at 180 days post-partum. A value of approximately 7.0 for the pH for mature equine milk was reported by Kücükcetin et al. (2003), but Pagliarini et al. (1993) reported an average value of approximately 7.2. The pH of bovine milk is generally between 6.5 and 6.7 (Singh et al. 1997) and increases during lactation (Tsioulpas et al. 2007). These differences are presumably related to differences in protein and salt composition of the milks.

FREEZING POINT

The freezing point of milk is directly related to the concentrations of water-soluble compounds therein. Fat globules and proteins have a negligible influence on freezing point, with the main effect arising from lactose and minerals. A freezing point of −0.554°C (Pagliarini et al. 1993) or −0.548°C (Neseni et al. 1958) has been reported for equine milk, whereas the vast majority of bovine milk samples have a freezing point in the range −0.512 to −0.550°C (Singh et al. 1997). The lower freezing point of equine milk is probably related to its higher lactose content.

VISCOSITY

Equid milks are less viscous than bovine milk due to a lower total solids content.

COLOUR

Equid milk may be expected to be less white than bovine milk due to its low protein content and large casein micelles but this is not the case and equid milk is considerably whiter due to the absence of β-carotene that confers a yellow colour to bovine milk.

PROCESSING OF EQUID MILK

Because of its unique physico-chemical properties outlined earlier, the processing of equine and asinine milk into traditional dairy products is not possible; cheese is not produced from these milks as a firm curd is not formed on renneting. Equid milk will form a weak coagulum under acidic conditions and this is exploited in the production of yoghurt-type products with reputed probiotic and therapeutic properties. Traditionally, and to date, the only significant product from equine milk is the fermented product, koumiss, the production and properties of which are described below in section 'Koumiss'. Interest in koumiss production has grown recently which may be attributed to the fact that, worldwide, the overall consumption of fermented milk products has grown faster than the consumption of fresh milk (IDF 2009).

Fermentation is one of the oldest methods for preserving milk and probably dates back approximately 10,000 years to the Middle East where the first organised agriculture occurred. Traditional fermented milk products have been developed independently worldwide and were, and continue to be, especially important in areas where transportation, pasteurisation and refrigeration facilities are inadequate. Worldwide, milk from eight species of domesticated mammals (cow, buffalo, sheep, goat, camel, horse, reindeer and yak) have been used to produce traditional fermented milk products. There are three categories of fermented milks, those resulting from lactic fermentations, yeast-lactic fermentations and mould (*Geotrichum candidum*)-lactic fermentations. Koumiss and kefir belong to the yeast-lactic fermentation group where alcoholic fermentation by yeasts is used

in combination with a lactic acid fermentation (Tamine and Marshall 1984). The conversion of milk into a fermented product has several important advantages; as well as being a means of preservation, it also improves taste and digestibility and increases the variety of food. Current interest in the health benefits of fermented milks started with the theory of longevity proposed by the Russian microbiologist, Elie Metchnikoff (1845–1918); he claimed that people who consumed fermented milks lived longer as lactic acid bacteria from the fermented product colonised the intestine and inhibited 'putrefaction' caused by harmful bacteria (a probiotic effect), thereby slowing down the aging process. Nowadays, the principal effects of probiotics are thought to be: improved gastrointestinal transit time of digesta, bowel function and glycemic index; some reports claim that they have an anticarcinogenic effect (see McIntosh 1996).

Further details on the fermentation of milk can be found in many publications including: Tamine and Marshall (1984); Koroleva (1991); Kurmann et al. (1992); Nakazawa and Hosono (1992); Surono and Hosono (2002).

KOUMISS

Koumiss (Kumys), fermented equine milk, is widely consumed in Russia, Mongolia and Kazakhstan, primarily for its therapeutic value. Russians, in particular, have long advocated the use of koumiss for a wide variety of illnesses but the variable microbiology of these products has made it difficult to confirm any theoretical basis for the claims (Tamine and Robinson 1999). In Mongolia, koumiss is the national drink (Airag) and a high-alcoholic drink made by distilling koumiss, called Arkhi, is also produced (Kanbe 1992). *Per caput* consumption of koumiss in Mongolia is estimated to be about 50 L/yr.

Koumiss is still manufactured in remote areas of Mongolia by traditional methods but with increased demand elsewhere it is now produced under more controlled and regulated conditions. Traditional koumiss (from fresh raw milk) was prepared by seeding milk with a mixture of bacteria and yeasts using part of the previous day's product as an inoculum. The milk was held in a leather sack called a 'turdusk' (also called a 'saba' or 'burduk'), made from smoked horsehide taken from the thigh area, that is, it has a broad bottom and a narrow, long, sleeve with a capacity of 25–30 L, fermentation takes from 3 to 8 hours. In the 1960s, the microbial population was analysed and found to consist mainly of *Lactobacillus delbrueckii* subsp. *bulgaricus*, *Lactobacillus casei*, *Lactococcus lactis* subsp. *lactis*, *Kluveromyces fragilis* and *Saccharomyces unisporus* (Tamine and Marshall 1984). The lactic acid bacteria are responsible for acid production and the yeasts for the production of ethanol and carbon dioxide. During the mixing and maturation stages of production, more equine milk is usually added to control the levels of acidity and ethanol. The whole process is poorly controlled and often results in a product with an unpleasant taste due to the presence of too much yeast or excessive acidification. Turdusks, often containing fermented caprine milk from the previous season, were stored in a cool place over winter and the culture was reactivated when required by gradually filling the turdusk with equine milk over about 5 days (Tamine and Marshall 1984).

Koumiss contains about 90% moisture, 2–2.5% protein (1.2% casein and 0.9% whey proteins), 4.5–5.5% lactose, 1–1.3% fat and 0.4–0.7% ash, as well as the end-products of microbial fermentation, that is, lactic acid (1.8%), ethanol (0.6–2.5%) and CO_2 (0.5–0.9%) and provides 37 to 40 kCal/100 mL). After production, koumiss contains between 0.6 and 3% ethanol and is effervescent. Koumiss is thought to be more effective than raw equine milk in disease treatment due to the additional peptides and bactericidal substances produced during microbial metabolism (Doreau and Martin-Rosset 2002).

In the last decade, technological advances have been made in the manufacture of koumiss, such as the development of blends of microorganisms in starter cultures that enhance flavour development and extend the shelf life up to 14 days. The production of koumiss and other fermented milk products is carried out using a more standardised protocol for manufacture and is of considerable interest for increasing the market and consumption of equine milk products in countries where it has not normally been consumed (Di Cagno et al. 2004). As well as pasteurising the raw equine milk, pure cultures of lactobacilli such as *Lb. delbrueckii* subsp. *bulgaricus* and yeasts are used for koumiss manufacture. The use of *Saccharomyces lactis* is considered best for ethanol production (2–5%) and *S. cartilaginosus* is sometimes used for its antibiotic activity against *Mycobacterium tuberculosis* (Park et al. 2006). Other microorganisms such as *Candida* spp., *Torula* spp., *Lb. acidophilus* and *Lb. lactis* may also be used in koumiss production (Surono and Hosono 2002). A protocol for the manufacture of commercial koumiss is presented in Figure 26.6. The characteristics of a good koumiss are optimal when lactic and alcoholic fermentations proceed simultaneously so that the products of fermentation occur in definite proportions. As well as lactic acid, ethanol and CO_2, volatile acids and other compounds are formed which are important for aroma and taste and approximately 10% of equine milk proteins are hydrolysed. Products with varying amounts of lactic acid and ethanol are produced and generally 3 categories of koumiss are recognised: mild (0.6–0.8% acidity, 0.7–1.0% alcohol; medium (0.8–1.0% acidity, 1.1–1.8% alcohol) and strong (1.0–1.2% acidity, 1.8–2.5% alcohol (Tamine and Marshall 1984).

The presence of a high level of thermostable Lyz in equine milk may interfere with the activity of some starter microorganisms in the production of fermented products and thus cause problems in the processing of equine milk. Di Cagno et al. (2004) who heated equine milk to 90°C for 3 minutes to inactivate Lyz, produced an acceptable fermented product. In sensory tests, fermented equine milk generally scores low and, in an attempt to enhance the rheological and sensory properties of fermented products made from equine milk, Di Cagno et al. (2004) fortified equine milk with bovine Na caseinate (1.5 g.100^{-1}g), pectin (0.25 g.100^{-1}g) and threonine (0.08 g.100^{-1}g). The resultant product had good microbiological, rheological and sensory characteristics after 45 days at 4°C. Fermented unmodified equine milk had an unacceptable viscosity and scored very low in comparison to fortified products for appearance, consistency and taste.

Research has turned also to producing koumiss-like products from bovine milk, which must be modified to make it suitable for

Figure 26.6. Schematic for the production of koumiss. (Based on Berlin 1962.)

bulgaricus and *Kluyveromyces marxianus* var. *marxianus* or var. *lactis* as starter culture (Kücükcetin et al. 2003). Koumiss has also been made from diluted bovine milk supplemented with lactose and, more successfully, from bovine milk mixed with concentrated whey using a starter culture of *Kluyveromyces lactis* (AT CC 56498), *Lb. delbrueckii* subsp. *bulgaricus* and *Lb. acidophilus*. Starter cultures for koumiss manufacture from bovine milk may also include *Saccharomyces lactis* (high antimicrobial activity against *Mycobacterium tuberculosis*) in order to retain the 'anti-tuberculosis image' of equine milk (Kücükcetin et al. 2003). More recently, bovine milk has been modified to approximate the composition of mares' milk using a series of membrane filtration steps and a starter culture (*Kluyveromyces lactis*, *Lb. delbrueckii* subsp. *bulgaricus* and *Lb. acidophilus*) that ensures consistent fermentation; the resulting product was found to be very similar to koumiss with respect to pH, titratable acidity, ethanol content, proteolytic activity, apparent viscosity and microbial composition, both when fresh and stored (15 days at 4°C) (Kücükcetin et al. 2003).

The physico-chemical and microbiological properties of asinine milk, similar to equine milk, such as low microbiological load and high Lyz make it a good substrate for the production of fermented products with probiotic *Lactobacillus* strains. Coppola et al. (2002) incubated asinine milk with the probiotic *Lb. rhamnosus* (AT 194, GTI/1, GT 1/3) and found that the strain is unaffected by the high Lyz activity in the milk and remained viable after 15 days at 4°C and pH 3.7–3.8. *Lb. rhamnosus* inhibits the growth of most harmful bacteria in the intestine and acts as a natural preservative in yoghurt-type products, considerably extending shelf life. Chiavari et al. (2005) produced fermented beverages from asinine milk using a mixed culture of *Lb. rhamnosus* (AT 194, CLT 2.2) and *Lb. casei* (LC 88) and in all cases found a high level of viable bacteria after 30 days storage. Some sensory differences were recorded for the fermented drinks and those made with the *Lb. casei* strain developed a more acceptable and balanced aroma than the boiled vegetable/acidic taste and aroma of the products made with *Lb. rhamnosus*.

OTHER PRODUCTS FROM EQUID MILK

As sales of equine milk have increased considerably in recent years, research is now focused on the development of new fermented products or new methods for extending the shelf life of existing products, while maintaining some of the unique components of equine milk. The ability of milk to withstand relatively high processing temperatures is very important from a technological point of view. The whey proteins in equine milk are much more thermostable than those of bovine milk. Heat treatment at 80°C × 80 s causes only a 10–15% decrease in non-casein nitrogen, with a marked decrease evident only when the temperature is increased above 100°C (Bonomi et al. 1994). Lf and equine BSA are the most heat-sensitive but are not completely denatured until the temperature reaches 130°C x 10 min. β-Lg and α-La are almost completely denatured at temperatures over 130°C and Lyz at temperatures greater than 110°C (68% residual Lyz activity after heating at 82°C for 15 minutes (Jauregui-Adell 1975).

koumiss production. Methods have been developed, with varying degrees of success, where a single constituent of bovine milk has been altered to resemble that of equine milk, for example the carbohydrate content has been increased or the protein content reduced but, until recently both had not been altered simultaneously. Koumiss of reasonable quality has been produced successfully from whole or skimmed bovine milk containing added sucrose using a mixture of *Lb. acidophilus*, *Lb. delbrueckii* ssp.

NUTRITIONAL AND BIOMEDICAL PROPERTIES OF EQUID MILK

It is claimed that fresh and fermented equid milk relieve metabolic and intestinal problems while having a gut-cleansing effect coupled with 'repair' of the intestinal micro-flora. It is claimed to give relief from stomach ulcers, high blood pressure, high cholesterol and liver problems and is also recommended as an aid in the treatment of cancer patients. The recommended amount of equine milk is 250 mL/d. The most significant use of equid milk is as a substitute for bovine milk for patients with cows' milk protein allergy (CMPA); limited research has shown that both equine and asinine milks are generally tolerated well by CMPA patients. The use of equine milk in the production of cosmetics is relatively new and includes soaps, creams and moisturisers (Doreau and Martin-Rosset 2002). At present, equine milk is available in several forms: frozen milk, frozen yoghurt-type drink, lyopholised powder, shampoos and various cosmetic and medicinal creams. Lyopholised equine colostrum is available and used in the high-value horse industry to feed orphaned foals. Marconi and Panfili (1998) suggested that research is required to identify optimum drying and storage conditions for powdered equine milk for retention of some of the unique characteristics of raw milk, including high levels of whey proteins, PUFAs, lysine, tocopherols and vitamin C which are partially destroyed in the preparation of commercial powdered equine milk. Asinine milk is used to make ice cream and other desserts and also a fermented milk product. To improve the nutritive value of asinine milk and increase its overall energy content for human nutrition, it is frequently supplemented with approximately 4% medium-chain TGs (Salimei 2011).

Cow Milk Protein Allergy

Equine and asinine milk, with a composition close to that of human milk, may be good nutritional sources for the neonate when breast milk is not available. Bovine milk or bovine milk products are used traditionally as substitutes for human milk in infant nutrition but bovine milk is considerably different from human milk in terms of its macro- and micro-nutrients and the absorption rates of vitamins and minerals from the two milks are different, which can be problematic for infants. CMPA is an IgE-mediated type I allergy, which may be life-threatening, and is defined as a set of immunologically mediated adverse reactions which occur following the ingestion of milk, affecting from 2 to 6% of children in their first year of life. About 50% of affected children recover after the age of one and 80–90% of those affected recover by 5 years of age (Caffarelli et al. 2010). The high frequency of CMPA in infants and children is thought to be due to an incomplete gut mucosal barrier, increased gut permeability to large molecules and immature local and systemic responses which are aided by breast-milk which facilitates gut maturation and provides passive protection against bacteria and antigens (Hill 1994).

The difference between bovine milk protein allergy and lactose intolerance is of particular interest and it is an area which causes much confusion. CMPA is a food allergy, that is an adverse immune reaction to a food protein that is normally harmless to the non-allergic individual. Lactose intolerance is a non-allergic food hypersensitivity due to a deficiency of the enzyme β-galactosidase (lactase), required to hydrolyse lactose. Lactase deficiency manifests as abdominal symptoms and chronic diarrhoea after ingestion of milk (see Bindslev-Jensen 1998, Vesa et al. 2000). Lactose intolerance is not a disease or malady; 70% of the world's population is lactose-intolerant. Adverse effects of lactose intolerance occur at a much higher level of milk consumption than that which causes milk allergy.

CMPA is important because bovine milk is the first foreign antigen ingested in large quantities in early infancy. Reviews on CMPA include: Hill (1994); Hill and Hosking (1996); Taylor (1986); Høst (1988, 1991); Bindslev-Jensen (1998); Wal (2002, 2004); El-Agamy (2007); Apps and Beattie (2009). Because β-Lg is absent from human milk, it has commonly been considered to be the most important cows' milk allergen (Goldman et al. 1963, Ghosh et al. 1989) although other whey proteins (Jarvinen et al. 2001) and caseins (Savilahti and Kuitunen 1992, Restani et al. 1995) have also been implicated in allergic reactions. In children, β-Lg is the major allergen, whereas casein appears to be the most allergenic for adults. The resistance of β-Lg to proteolysis allows the protein to remain intact through the gastrointestinal tract with the possibility of being absorbed across the gut mucosa. Ingested β-Lg has been detected in human milk and could be responsible for colic in breast-fed infants and the sensitisation of infants, predisposing them to allergies (Jakobsson and Lindberg 1978, Kilshaw and Cant 1984, Stuart et al. 1984, Jakobsson et al. 1985, Axelsson et al. 1986).

The choice of substitute for cows' milk in cases of CMPA depends on two major factors, that is, nutritional adequacy and allergenicity; cost and taste must also be taken into account. Many soy or hydrolysate (casein-based, and more recently, whey protein-based) formulae are available for treatment of CMPA but they can themselves induce allergic reactions. Heat treatment of milk may destroy heat-labile proteins, especially BSA and Igs, and change the antigenic properties of other whey proteins, such as β-Lg and α-la, although caseins need severe heat treatment ($121°C \times 20$ minutes) to reduce sensitising capacity (Hill 1994). Enzymatic treatment of milk proteins may result in products with an unacceptable taste due to bitterness arising from the production of peptides and amino acids and such peptides may, in fact, be allergenic (Schmidt et al. 1995, Sélo et al. 1999, El-Agamy 2007).

Many clinical studies have been carried out on the use of the milk of different species in infant nutrition, for example goat, sheep (Restani et al. 2002), camel (El-Agamy 2007), buffalo (El-Agamy 2007), horse and donkey (Iacono et al. 1992, Carroccio et al. 2000, El-Agamy et al. 1997, Businco et al. 2000, Monti et al. 2007). Results on the benefits of such milks are conflicting and infants with CMPA may suffer allergic reactions to buffalo, goat, sheep, donkey or mare milk proteins due to positive immunological cross-reaction with their counterparts in cows' milk (El-Agamy 2007). Lara-Villoslada et al. (2005) found that the balance between casein and whey proteins may be important in determining the allergenicity of bovine milk proteins in humans and that modification of this balance may reduce the

allergenicity of bovine milk; a readjustment of the casein:whey proteins ratio to 40:60 was found to make the bovine milk significantly less allergenic. Presumably, equine and asinine milk, with a ratio of casein:whey proteins close to that in human milk, are potentially good substitutes for human milk. It is noteworthy that the study by Lara-Villoslada et al. (2005) was carried out using mice as subjects and the increased level of β-Lg (a major bovine milk allergen) in bovine milk adjusted to 40:60, casein:whey was not considered.

CROSS-REACTIVITY OF MILK PROTEINS

Cross-reaction occurs when two food proteins have similar amino acid sequences or when the three-dimensional conformation makes two molecules similar in their capacity to bind specific antibodies (Restani et al. 2002). Cross-reactivity of proteins from different species generally reflects the phylogenetic relations between animal species, for example homologous proteins from vertebrates often cross-react. A comprehensive study on the subject by Jenkins et al. (2007) highlights some interesting

points, especially concerning the potential allergenicity of caseins from different species. The authors set out to determine how closely a foreign protein has to resemble a human homologue before it actually loses its allergenic affect. A high degree of similarity to human homologues would, presumably, imply that a foreign animal food protein would be much less likely than a protein with little or no similarity to its human homologue to be allergenic in human subjects. In addition, the study of potential animal allergens must take into account the ability of the human immune system to discriminate between its own proteins, that is an autoimmune response, and those from another species which have a high similarity, that is how closely a foreign protein has to resemble a human homologue before it loses its ability to act as an allergen? (Spitzauer 1999). Table 26.17 gives the percentage homology of α-$_{S1}$-, α-$_{S2}$ and β-caseins from different species to bovine and human homologues. Known allergens are less than 53% identical to human sequences. Natale et al. (2004) found that 90% of a group of infants with CMPA had serum IgE against bovine α_{S2}-casein, 55% against bovine α_{S1}-casein and only 15% against bovine β-casein, which is closest in amino acid

Table 26.17. Homology (percentage) Between Milk Proteins from Different Species and Their Human Homologues

Casein	Accession Code	Percent Identity to Closest	
		Bovine Homolog	Human Homolog
α-$_{S1}$-Casein			
Cow	P02662	100	29
Goat	Q8M1H4	88	29

composition to human β-casein. Caprine and ovine milk proteins are more closely related to each other than either is to bovine milk proteins, thus explaining why an individual allergic to goats' milk cheese may exhibit high IgE cross-reactivity with sheep's milk proteins but could tolerate cow's milk and its products.

Allergy to equine milk appears to be rare and, to date, only two documented cases have been reported. Fanta and Ebner (1998) reported the case of an individual who experienced sensitisation to horse dander allergen and subsequently produced IgE antibodies on ingestion of equine milk which was prescribed to 'strengthen' her immune system. Gall et al. (1996) demonstrated the existence of an IgE-mediated equine milk allergy in one patient, caused by low MW heat-labile proteins, most likely α-La and β-Lg, without cross-reaction to the corresponding whey proteins from bovine milk. Presumably, the previous cases are not isolated incidents and as the consumption of equine milk and its products increases, it is likely that further cases will be reported.

Bevilaçqua et al. (2001) tested the capacity of goats' milk with low or high α_{s1}-casein content to induce milk protein sensitisation in guinea pigs and found significantly less sensitisation by milk with low α_{s1}-casein. This may represent an important attribute of the low α_{s1}-casein content of equine milk for use in human allergology. The absence of α_{s2}-casein (and lack of α_{s1} casein in one donkey) and β-lg II in donkey milk reported by Criscione et al. (2009) could be potentially interesting for future research on the allergenicity of asinine milk; α_{s1}-casein and β-lg are scarce or absent in human milk and are considered to be the most significant proteins causing allergic reactions in children and adults.

SUMMARY

The characteristics of equine and asinine milk of interest in human nutrition include an exceptionally high concentration of polyunsaturated fatty acids, low cholesterol content, high lactose and low protein levels (Solaroli et al. 1993, Salimei et al. 2004), as well as high levels of vitamins A, B and C. The low fat and unique fatty acid profile of both equine and asinine milk results in low atherogenic and thrombogenic indices. Research has shown that human health is considerably improved when dietary fat intake is reduced and, more importantly, when the ratio of saturated to unsaturated fatty acids is reduced. The high lactose content of equid milk gives good palatability and improves intestinal absorption of calcium, which is important for bone mineralisation in children. The renal load of equine milk, based on levels of protein and inorganic substances, is equal to that of human milk, a further indication of its suitability as an infant food. Equine and asinine milk can be used for their prebiotic and probiotic activity and as alternatives for infants and children with CMPA and multiple food intolerances (Iacono et al. 1992, Carroccio et al. 2000).

The invigorating effect of equine milk may be, at least partially, due to its immunostimulating ability. Lyz, Lf and n-3 fatty acids have long been associated with the regulation of

phagocytosis of human neutrophils *in vitro* (Ellinger et al. 2002). The concentration of these compounds is exceptionally high in equine milk and the consumption of frozen equine milk significantly inhibits chemotaxis and respiratory burst, two important phases of the phagocytic process (Ellinger et al. 2002). This result suggests a potential anti-inflammatory effect by equine milk.

To be successful as a substitute for human milk in infant nutrition, equine milk must be capable of performing many biological functions associated with human milk. The presence of high concentrations of Lf, Lyz, n-3 and n-6 fatty acids in equine milk are good indicators of its potential role. However, the lack of research must be addressed to develop the potential of equine milk in the health and nutritional markets. Studies are required to bring the health claims for equine milk out of the realms of regional folklore. It seems reasonable to suggest that equine milk could be marketed as a dietary aid where the immune system is already depleted, that is, as a type of 'immuno-boost'. More than 30% of customers who purchase equine milk in the Netherlands are patients undergoing chemotherapy, who find equine milk helpful in counteracting the effects of the treatment. The composition of equine milk suggests a product with interesting nutritional characteristics with potential use in dietetics and therapeutics, especially in diets for the elderly, convalescent and newborns.

Future research should also include comprehensive characterisation of the proteins of different breeds of horse and donkey, with the possibility of selection of animals for specific proteins which could, in turn, optimise the nutritional and technological properties of the milks; the genetic control of α_s-, β- and κ-caseins as well as β-Lg in bovine and caprine milk has been researched, albeit in a somewhat limited manner, as has the effects of these proteins on the technological properties of both types of milk, for example colloidal stability, coagulation and curd strength. These characteristics can determine the physical and chemical behaviour of milk in the infant gastrointestinal tract with the result that digestion and availability of nutrients to the young may be affected (Cuthbertson 1999). Furthermore, genetic selection of certain breeds of horse and donkey may improve milk yield and lactation pattern and make the production of milk more cost effective.

27
Biochemistry of Fruits

Gopinadhan Paliyath, Krishnaraj Tiwari, Carole Sitbon, and Bruce D. Whitaker

Abstract: Fruits are major ingredients of human diet and provide several nutritional ingredients including carbohydrates, vitamins and functional food ingredients such as soluble and insoluble fibers, polyphenols and carotenoids. Biochemical changes during fruit ripening make the fruit edible by making them soft, changing the texture through the breakdown of cell wall, converting acids or stored starch into sugars and causing the biosynthesis of pigments and flavour components. Fruits are processed into several products to preserve these qualities.

INTRODUCTION

Because of various health benefits associated with the consumption of fruits and various products derived from fruits, these are at the centre stage of human dietary choices in recent days. The selection of trees that produce fruits with ideal edible quality has been a common process throughout human history. Fruits are developmental manifestations of the seed-bearing structures in plants, the ovary. After fertilisation, the hormonal changes induced in the ovary result in the development of the characteristic fruit that may vary in ontogeny, form, structure and quality. Pome fruits such as apple and pear are developed from the development of the thalamus in the flower. Drupe fruits, such as cherry, peach, plum, apricot and so on, are developed from the ovary wall (mesocarp) enclosing a single seed. Berry fruits such as tomato possess the seeds embedded in a jelly-like pectinaceous matrix, with the ovary wall developing into the flesh of the fruit. Cucumbers and melons develop from an inferior ovary. Citrus fruits belong to the class hesperidium, where the ovary wall develops as a protective structure surrounding the juice-filled locules that become the edible part of the fruit. In strawberry, the seeds are located outside the fruit, and it is the receptacle of the ovary (central portion) that develops into the edible part. The biological purpose of the fruit is to attract vectors that help in the dispersal of the seeds. For this, the fruits have developed various organoleptic (stimulatory to organs) characteristics that include attractive colour, flavour and taste. The biochemical characteristics and pathways in the fruits are developmentally structured to achieve these goals. The nutritional and food qualities of fruits arise as a result of the accumulation of components derived from these intricate biochemical pathways. In terms of production and

volume, tomato, orange, banana and grape are the major fruit crops used for consumption and processing around the world (Kays 1997).

BIOCHEMICAL COMPOSITION OF FRUITS

Fruits contain a large percentage of water, which can often exceed 95% by fresh weight. During ripening, activation of several metabolic pathways often leads to drastic changes in the biochemical composition of fruits. Fruits such as banana store starch during development, and hydrolyse the starch to sugars during ripening, that also results in fruit softening. Most fruits are capable of photosynthesis, store starch and convert them to sugars during ripening. Fruits such as apple, tomato, grape and so on have a high percentage of organic acids, which decreases during ripening. Fruits also contain large amounts of fibrous materials such as cellulose and pectin. The degradation of these polymers into smaller water-soluble units during ripening leads to fruit softening as exemplified by the breakdown of pectin in tomato and cellulose in avocado. Secondary plant products are major compositional ingredients in fruits. Anthocyanins are the major colour components in grape, blueberry, apple and plum; carotenoids, specifically lycopene and carotene, are the major components that impart colour in tomato and watermelon. Aroma is derived from several types of compounds that include monoterpenes (as in lime, orange), ester volatiles (ethyl, methyl butyrate in apple, isoamyl acetate in banana), simple organic acids such as citric and malic acids (citrus fruits, apple) and small chain aldehydes such as hexenal and hexanal (cucumber). Fruits are also rich in vitamin C. Lipid content is quite low in fruits, the exceptions being avocado and olives, in which triacylglycerols (oils) form the major storage components. The amounts of proteins are usually low in most fruits.

Carbohydrates, Storage and Structural Components

As the name implies, carbohydrates are organic compounds containing carbon, hydrogen and oxygen. Basically, all carbohydrates are derived by the photosynthetic reduction of CO_2 to the pentoses (ribose, ribulose) and hexoses (glucose, fructose), which are also intermediates in the metabolic pathways. Polymerisation of several sugar derivatives leads to various storage (starch, inulin) and structural components (cellulose, pectin).

During photosynthesis, the glucose formed is converted to starch and stored as starch granules. Glucose and its isomer fructose, along with phosphorylated forms (glucose-6-phosphate, glucose-1,6- diphosphate, fructose-6-phosphate and fructose-1,6-diphosphate), can be considered to be the major metabolic hexose pool components that provide carbon skeleton for the synthesis of carbohydrate polymers. Starch is the major storage carbohydrate in fruits. There are two molecular forms of starch, amylose and amylopectin and both components are present in the starch grain. Starch is synthesised from glucose phosphate by the activities of a number of enzymes designated as ADP-glucose pyrophosphorylase, starch synthase and a starch-branching en-

zyme. ADP-glucose pyrophosphorylase catalyses the reaction between glucose-1-phosphate and ATP that generates ADP-glucose and pyrophosphate. ADP-glucose is used by starch synthase to add glucose molecules to amylose or amylopectin chain, thus increasing their degree of polymerisation. By contrast to cellulose that is made up of glucose units in β-1,4-glycosidic linkages, the starch molecule contains glucose linked by α-1,4-glycosidic linkages. The starch branching enzyme introduces glucose molecules through α-1,6- linkages which further gets extended into linear amylose units with α-1,4- glycosidic linkages. Thus, the added glucose branch points (α-1,6-linkages) serve as sites for further elongation by starch synthase, thus resulting in a branched starch molecule, also known as amylopectin.

Cell wall is a complex structure composed of cellulose and pectin, derived from hexoses such as glucose, galactose, rhamnose and mannose, and pentoses such as xylose and arabinose, as well as some of their derivatives such as glucuronic and galacturonic acids (Negi and Handa 2008). A model proposed by Keegstra et al. (1973) describes the cell wall as a polymeric structure constituted by cellulose microfibrils and hemicellulose embedded in the apoplastic matrix in association with pectic components and proteins. In combination, these components provide the structural rigidity that is characteristic to the plant cell. Most of the pectin is localised in the middle lamella. Cellulose is biosynthesised by the action of β-1,4-glucan synthase enzyme complexes that are localised on the plasma membrane. The enzyme uses uridine diphosphate glucose (UDPG) as a substrate, and by adding UDPG units to small cellulose units, extends the length and polymerisation of the cellulose chain. In addition to cellulose, there are polymers made of different hexoses and pentoses known as hemicelluloses, and based on their composition, they are categorised as xyloglucans, glucomannans and galactoglucomannans. The cellulose chains assemble into microfibrils through hydrogen bonds to form crystalline structures. In a similar manner, pectin is biosynthesised from UDP-galacturonic acid (galacturonic acid is derived from galactose, a six carbon sugar), as well as other sugars and derivatives and includes galacturonans and rhamnogalacturonans that form the acidic fraction of pectin. As the name implies, rhamnogalacturonans are synthesised primarily from galacturonic acid and rhamnose. The acidic carboxylic groups complex with calcium that provide the rigidity to the cell wall and the fruit. The neutral fraction of the pectin comprises polymers such as arabinans (polymers of arabinose), galactans (polymers of galactose) or arabinogalactans (containing both arabinose and galactose). All these polymeric components form a complex three-dimensional network stabilised by hydrogen bonds, ionic interactions involving calcium, phenolic components such as diferulic acid and hydroxyproline-rich glycoproteins (Fry 1986, Negi and Handa 2008). It is also important to visualise that these structures are not static and the components of cell wall are constantly being turned over in response to growth conditions.

Lipids and Biomembranes

By structure, lipids can form both structural and storage components. The major forms of lipids include fatty acids,

diacyl- and triacylglycerols, phospholipids, sterols, and waxes that provide an external barrier to the fruits. Fruits in general are not rich in lipids with the exception of avocado and olives that store large amounts of triacylglycerols or oil. As generally observed in plants, the major fatty acids in fruits include palmitic (16:0), stearic (18:0), oleic (18:1), linoleic (18:2) and linolenic (18:3) acids. Among these, oleic, linoleic and linolenic acids possess an increasing degree of unsaturation. Olive oil is rich in triacylglycerols containing the monounsaturated oleic acid and is considered as a healthy ingredient for human consumption.

Compartmentalisation of cellular ingredients and ions is an essential characteristic of all life forms. The compartmentalisation is achieved by biomembranes, formed by the assembly of phospholipids and several neutral lipids that include diacylglycerols and sterols, the major constituents of the biomembranes. Virtually, all cellular structures include or are enclosed by biomembranes. The cytoplasm is surrounded by the plasma membrane, the biosynthetic and transport compartments such as the endoplasmic reticulum and Golgi bodies form an integral network of membranes within the cell. Photosynthesis, which converts light energy into chemical energy, occurs on the thylakoid membrane matrix in the chloroplast, and respiration, which further converts chemical energy into more usable forms, occurs on the mitochondrial cristae. All these membranes have their characteristic composition and enzyme complexes to perform their designated function.

The major phospholipids that constitute the biomembranes include phosphatidylcholine, phosphatidylethanolamine, phosphatidylglycerol and phosphatidylinositol. Their relative proportion may vary from tissue to tissue. In addition, metabolic intermediates of phospholipids such as phosphatidic acid, diacylglycerols, free fatty acids and so on are also present in the membrane in lower amounts. Phospholipids are integral functional components of hormonal and environmental signal transduction processes in the cell. Phosphorylated forms of phosphatidylinositol such as phosphatidylinositol-4- phosphate and phosphatidylinositol-4,5-bisphosphate are formed during signal transduction events, though their amounts can be very low. The membrane also contains sterols such as sitosterol, campesterol and stigmasterol, as well as their glucosides, and they are extremely important for the regulation of membrane fluidity and function (Whitaker 1988, 1991, 1993, 1994).

Biomembranes are bilamellar layers of phospholipids. The amphipathic nature of phospholipids having hydrophilic head groups (choline, ethanolamine, etc.) and hydrophobic fatty acyl chains, thermodynamically favour their assembly into bilamellar or micellar structures when exposed to an aqueous environment. In a biomembrane, the hydrophilic headgroups are exposed to the external aqueous environment. The phospholipid composition between various fruits may differ, and within the same fruit, the inner and outer lamella of the membrane may have a different phospholipids composition. Such differences may cause changes in polarity between the outer and inner lamellae of the membrane, and lead to the generation of a voltage across the membrane. These differences usually become operational during signal transduction events.

An essential characteristic of the membrane is its fluidity. The fluid-mosaic model of the membrane (Singer and Nicholson 1972) depicts the membrane as a planar matrix comprising phospholipids and proteins. The proteins are embedded in the membrane bilayer (integral proteins) or are bound to the periphery (peripheral proteins). The nature of this interaction results from the structure of the proteins. If the proteins have a much larger proportion of hydrophobic amino acids, they would tend to become embedded in the membrane bilayer. If the protein contains more hydrophilic amino acids it may tend to prefer a more aqueous environment, and thus remain as a peripheral protein. In addition, proteins may be covalently attached to phospholipids such as phosphatidylinositol. Proteins that remain in the cytosol may also become attached to the membrane in response to an increase in cytosolic calcium levels. The membrane is a highly dynamic entity. The semi-fluid nature of the membrane allows for the movement of phospholipids in the plane of the membrane, and between the bilayers of the membrane. The proteins are also mobile within the plane of the membrane. However, this process is not always random and is regulated by the functional assembly of proteins into metabolons (functional assembly of enzymes and proteins, e.g., photosynthetic units in thylakoid membrane, respiratory complexes in the mitochondria, cellulose synthase on plasma membrane, etc.), their interactions with the underlying cytoskeletal system (network of proteins such as actin and tubulin), and the fluidity of the membrane.

The maintenance of homeostasis (life processes) requires the maintenance of the integrity and function of discrete membrane compartments. This is essential for the compartmentalisation of ions and metabolites, which may otherwise destroy the cell. For instance, calcium ions are highly compartmentalised within the cell. The concentration of calcium is maintained at the millimolar levels within the cell wall compartment (apoplast), endoplasmic reticulum and the tonoplast (vacuole). This is achieved by energy-dependent transport of calcium from the cytoplasm into these compartments by ATPases. As a result, the cytosolic calcium levels are maintained at low micromolar (<1 μM) levels. Maintenance of this concentration gradient across the membrane is a key requirement for the signal transduction events, as regulated entry of calcium into the cytosol can be achieved simply by opening calcium channels. Calcium can then activate several cellular biochemical reactions that mediate the response to the signal. Calcium is pumped back into the storage compartments when the signal diminishes in intensity. In a similar manner, cytosolic pH is highly regulated by the activity of proton ATPases. The pH of the apoplast and the vacuole is maintained near four, whereas the pH of the cytosol is maintained in the range of 6–6.5. The pH gradient across the membrane is a key feature that regulates the absorption, or extrusion of other ions and metabolites such as sugars. The cell could undergo senescence if this compartmentalisation is lost.

There are several factors that affect the fluidity of the membrane. The major factor that affects the fluidity is the type and proportion of acyl chain fatty acids of the phospholipids. At a given temperature, a higher proportion of unsaturated fatty acyl chains (oleic, linoleic, linolenic) in the phospholipids can increase the fluidity of the membrane. An increase in saturated

fatty acids such as palmitic and stearic acids can decrease the fluidity. Other membrane components such as sterols, and degradation products of fatty acids such as fatty aldehydes, alkanes and so on can also decrease the fluidity. Based on the physiological status of the tissue, the membrane can exist in either a liquid crystalline state (where the phospholipids and their acyl chains are mobile) or a gel state where they are packed as rigid ordered structures and their movements are much restricted. The membrane usually has co-existing domains of liquid crystalline and gel phase lipids depending on growth conditions, temperature, ion concentration near the membrane surface and so on. The tissue has the ability to adjust the fluidity of the membrane by altering the acyl lipid composition of the phospholipids. For instance, an increase in the gel phase lipid domains resulting from exposure to cold temperature could be counteracted by increasing the proportion of fatty acyl chains having a higher degree of unsaturation, and, therefore, a lower melting point. Thus, the membrane will tend to remain fluid even at a lower temperature (Whitaker 1991, 1992, 1993, 1994). An increase in gel phase lipid domains can result in the loss of compartmentalisation. The differences in the mobility properties of phospholipid acyl chains can cause packing imperfections at the interface between gel and liquid crystalline phases, and these regions can become leaky to calcium ions and protons that are highly compartmentalised. The membrane proteins are also excluded from the gel phase into the liquid crystalline phase. Thus, during examinations of membrane structure by freeze fracture electron microscopy, the gel phase domains can appear as regions devoid of proteins (Paliyath and Thompson 1990).

PROTEINS

Fruits, in general, are not very rich sources of proteins. During the early growth phase of fruits, the chloroplasts and mitochondria are the major organelles that contain structural proteins. The structural proteins include the light-harvesting complexes in chloroplast or the respiratory enzyme/protein complexes in mitochondria. Ribulose-bis-phosphate carboxylase/oxygenase (Rubisco) is the most abundant enzyme in photosynthetic tissues. Fruits do not store proteins as an energy source. The green fruits such as bell peppers and tomato have a higher level of chloroplast proteins.

ORGANIC ACIDS

Organic acids are major components of some fruits. The acidity of fruits arises from the organic acids that are stored in the vacuole, and their composition can vary depending on the type of fruit. In general, young fruits contain more organic acids, which may decline during maturation and ripening due to their conversion to sugars (gluconeogenesis; eg. conversion of malic acid into glucose during ripening of apple). Some fruit families are characterised by the presence of certain organic acids. For example, fruits of oxalidaceae members (e.g., starfruit, *Averrhoa carambola*) contain oxalic acid, and fruits of the citrus family, rutaceae, are rich in citric acid. Apples contain malic acid and grapes are characterised by the presence of tartaric acid. In general, citric and malic acids are the major organic acids of fruits. Grapes contain tartaric acid as the major organic acid. During ripening, these acids can enter the citric acid cycle and undergo further metabolic conversions.

L-(+)tartaric acid is the optically active form of tartaric acid in grape berries. A peak in acid content is observed before the initiation of ripening, and the acid content declines on a fresh weight basis during ripening. Tartaric acid can be biosynthesised from carbohydrates and other organic acids. Radiolabelled glucose, glycolate and ascorbate were all converted to tartarate in grape berries. Malate can be derived from the citric acid cycle or through carbon dioxide fixation of pyruvate by the malic enzyme (NADPH-dependent malate dehydrogenase). Malic acid, as the name implies, is also the major organic acid in apples.

FRUIT RIPENING AND SOFTENING

Fruit ripening is a physiological event that results from a very complex and interrelated biochemical changes that occur in the fruits. Ripening is the ultimate stage of the development of the fruit, which entails the development of ideal organoleptic characters such as taste, colour and aroma that are important features of attraction for the vectors (animals, birds, etc.) responsible for the dispersal of the fruit, and thus the seeds, in the ecosystem. Human beings have developed an agronomic system of cultivation, harvest and storage of fruits with ideal food qualities. In most cases, the ripening process is very fast, and the fruits undergo senescence resulting in the loss of desirable qualities. An understanding of the biochemistry and molecular biology of the fruit ripening process has resulted in developing biotechnological strategies for the preservation of postharvest shelf life and quality of fruits (Negi and Handa 2008, Paliyath et al. 2008a).

A key initiator of the ripening process is the gaseous plant hormone ethylene. In general, all plant tissues produce a low, basal, level of ethylene. Based on the pattern of ethylene production and responsiveness to externally added ethylene, fruits are generally categorised into climacteric and non-climacteric fruits. During ripening, the climacteric fruits show a burst in ethylene production and respiration (CO_2 production). Non-climacteric fruits show a considerably low level of ethylene production. In climacteric fruits (apple, pear, banana, tomato, avocado, etc.), ethylene production can reach levels of 30–500 ppm (parts per million, microlitre/L), whereas in non-climacteric fruits (orange, lemon, strawberry, pineapple, etc.) ethylene levels usually are in the range of 0.1–0.5 ppm. Ethylene can stimulate its own biosynthesis in climacteric fruits, known as autocatalytic ethylene production. As well, the respiratory carbon dioxide evolution increases in response to ethylene treatment, termed as the respiratory climacteric. Climacteric fruits respond to external ethylene treatment by accelerating the respiratory climacteric and time required for ripening, in a concentration-dependent manner. Non-climacteric fruits show increased respiration in response to increasing ethylene concentration without accelerating the time required for ripening.

Ethylene biosynthetic pathway
Figure 27.1. Summary of ethylene biosynthesis and action during fruit ripening. ACC, 1-Aminocyclopropane 1- Carboxylic Acid.

Ethylene is biosynthesised through a common pathway that uses the amino acid methionine as the precursor (Yang 1981, Fluhr and Mattoo 1996) (Fig. 27.1). The first reaction of the pathway involves the conversion of methionine to S-adenosyl methionine (SAM) mediated by the enzyme methionine adenosyl transferase. SAM is further converted into 1-aminocyclopropane-1-carboxylic acid (ACC) by the enzyme ACC synthase. The sulphur moiety of methylthioribose generated during this reaction is recycled back to methionine by the action of a number of enzymes. ACC is the immediate precursor of ethylene and is acted upon by ACC oxidase to generate ethylene. ACC synthase and ACC oxidase are the key control points in the biosynthesis of ethylene. ACC synthase is a soluble enzyme located in the cytoplasm, with a relative molecular mass of 50 kDa (kiloDalton). ACC oxidase is found to be associated with the vacuolar or mitochondrial membrane. Using molecular biology tools, a cDNA (complementary DNA representing the coding sequences of a gene) for ACC oxidase was isolated from tomato (Hamilton et al. 1991) and is found to encode a protein with a relative molecular mass of 35 kDa. There are several isoforms of ACC-synthase. These are differentially expressed in response to wounding, other stress factors and at the initiation of ripening. ACC oxidase reaction requires Fe^{2+}, ascorbate and oxygen.

Regulation of the activities of ACC synthase and ACC oxidase is extremely important for the preservation of shelf life and qual-

ity in fruits. Inhibition of the ACC synthase and ACC oxidase gene expression by the introduction of their respective antisense cDNAs resulted in delayed ripening and better preservation of the quality of tomato (Hamilton et al. 1990, Oeller et al. 1991) and apple (Hrazdina et al. 2000) fruits. ACC synthase, which is the rate-limiting enzyme of the pathway, requires pyridoxal-5-phosphate as a cofactor, and is inhibited by pyridoxal phosphate inhibitors such as aminoethoxyvinylglycine (AVG) and aminooxy acetic acid (AOA). Field application of AVG as a growth regulator (Retain[TM], Valent Biosciences, Chicago) has been used to delay ripening in fruits such as apples, peaches and pears. Also, commercial storage operations employ controlled atmosphere with very low oxygen levels (1–3%) for long-term storage of fruits such as apples to reduce the production of ethylene, as oxygen is required for the conversion of ACC to ethylene.

In response to the initiation of ripening, several biochemical changes are induced in the fruit, which ultimately results in the development of ideal texture, taste, colour and flavour. Several biochemical pathways are involved in these processes as described in the subsequent text.

CARBOHYDRATE METABOLISM

Cell Wall Degradation

Cell wall degradation is the major factor that causes softening of several fruits. This involves the degradation of cellulose components, pectin components or both. Cellulose is degraded by the enzyme cellulase or β-1,4-glucanase. Pectin degradation involves the enzymes pectin methylesterase, polygalacuronase (pectinase) and β-galactosidase (Negi and Handa 2008). The degradation of cell wall can be reduced by the application of calcium as a spray or drench in apple fruits. Calcium binds and cross-links the free carboxylic groups of polygalacturonic acid components in pectin. Calcium treatment, therefore, also enhances the firmness of the fruits.

The activities of both cellulase and pectinase have been observed to increase during ripening of avocado fruits and result in their softening. Cellulase is an enzyme with a relative molecular mass of 54.2 kDa and formed by extensive post-translational processing of a native 54 kDa protein involving proteolytic cleavage of the signal peptide and glycosylation (Bennet and Christopherson 1986). Further studies have shown three isoforms of cellulose ranging in molecular masses between 50 and 55 kDa. These forms are associated with the endoplasmic reticulum, the plasma membrane and the cell wall (Dallman et al. 1989). The cellulase isoforms are initially synthesised at the style end of the fruit at the initiation of ripening, and the biosynthesis progressively increases towards the stalk end of the fruit with the advancement of ripening. Degradation of hemicelluloses (xyloglucans, glucomannans and galactoglucomannans) is also considered as an important feature that leads to fruit softening. Degradation of these polymers could be achieved by cellulases and galactosidases.

Loss of pectic polymers through the activity of polygalacturonases (PG) is a major factor involved in the softening of fruits

such as tomato. There are three major isoforms of PG responsible for pectin degradation in tomato, designated as PG1, PG2a and PG2b (Fischer and Bennet 1991). PG1 has a relative molecular mass of 100 kDa, and is the predominant form at the initiation of ripening. With the advancement of ripening, PG2a and PG2b isoforms increase, becoming the predominant isoforms in ripe fruit. The different molecular masses of the isozymes result from the post-translational processing and glycosylation of the polypeptides. PG2a (43 kDa) and PG2b (45 kDa) appear to be the same polypeptide with different degrees of glycosylation. PG1 is a complex of three polypeptides, PG2a, PG2b and a 38kDa subunit known as the β-subunit. The 38 kDa subunit is believed to exist in the cell wall space where it combines with PG2a and PG2b forming the PG1 isoform of PG. The increase in activity of PG1 is related to the rate of pectin solubilisation and tomato fruit softening during the ripening process.

Research into the understanding of the regulation of biosynthesis and activity of PG using molecular biology tools has resulted in the development of strategies for enhancing the shelf life and quality of tomatoes. PG mRNA was one of the first ripening-related mRNAs isolated from tomato fruits. All the different isoforms of PGs are encoded by a single gene. The PG cDNA which has an open reading frame of 1371 bases encodes a polypeptide having 457 amino acids, which includes a 24 amino acid signal sequence (for targeting to the cell wall space) and a 47 amino acid pro-sequence at the N-terminal end, which are proteolytically removed during the formation of the active PG isoforms. A 13 amino acid long C-terminal peptide is also removed resulting in a 373 amino acid long polypeptide, which undergoes different degrees of glycosylation resulting in the PG2a and PG2b isozymes. Complex formation among PG2a, PG2b and the 38-kDa subunit in the apoplast results in the PG1 isozyme (Grierson et al. 1986, Bird et al. 1988). In response to ethylene treatment of mature green tomato fruits which stimulates ripening, the levels of PG mRNA and PG are found to increase. These changes can be inhibited by treating tomatoes with silver ions, which interfere with the binding of ethylene to its receptor and initiation of ethylene action (Davies et al. 1988). Thus, there is a link between ethylene, PG synthesis and fruit softening.

Genetic engineering of tomato with the objective of regulating PG activity has yielded complex results. In the rin mutant of tomato which lacks PG and does not soften, introduction of a PG gene resulted in the synthesis of an active enzyme; however, this did not cause fruit softening (Giovannoni et al. 1989). As a corollary to this, introduction of the PG gene in the antisense orientation resulted in near total inhibition of PG activity (Smith et al. 1988). In both these cases, there was very little effect on fruit softening, suggesting that factors other than pectin de-polymerisation may play an integral role in fruit softening. Further studies using a tomato cultivar such as UC82B (Kramer et al. 1992) showed that antisense inhibition of ethylene biosynthesis or PG did indeed result in lowered PG activity, improved integrity of cell wall and increased fruit firmness during fruit ripening. As well, increased activity of pectin methylesterase, which removes the methyl groups from esterified galacturonic acid moieties, may contribute to the fruit softening process.

The activities of pectin degrading enzymes have been related to the incidence of physiological disorders such as "mealiness" or "wooliness" in mature unripened peaches that are stored at a low temperature. The fruits with such a disorder show a lack of juice and a dry texture. De-esterification of pectin by the activity of pectin methyl esterase is thought to be responsible for the development of this disorder. Pectin methyl esterase isozymes with relative molecular masses in the range of 32 kDa have been observed in peaches, and their activity increases after 2 weeks of low temperature storage. Polygalacuronase activity increases as the fruit ripens. The ripening fruits which possess both polygalacturonase and pectin methyl esterase do not develop mealy symptoms when stored at low temperature implicating the potential role of pectin degradation in the development of mealiness in peaches.

There are two forms of PG in peaches, the exo- and endo-PG. The endo-PG are the predominant forms in the freestone type of peaches, whereas the exo-PG are observed in the mesocarp of both freestone and clingstone varieties of peaches. As the name implies, exo-PG remove galacturonic acid moieties of pectin from the terminal reducing end of the chain, whereas the endo-PG can cleave the pectin chain at random within the chain. The activities of these enzymes increase during the ripening and softening of the fruit. Two exo-PG isozymes have been identified in peach, having a relative molecular mass of near 66 kDa. The exo-acting enzymes are activated by calcium. Peach endo-PG is observed to be similar to the tomato endo-PG. The peach endo-PG is inhibited by calcium. The freestone peaches possess enhanced activities of both exo-PG and endo-PG leading to a high degree of fruit softening. However, the clingstone varieties with low levels of endo-PG activity do not soften as the freestone varieties. In general, fruits such as peaches, tomatoes, strawberries, pears and so on, which soften extensively, possess high levels of endo-PG activity. Apple fruits which remain firm lack endo-PG activity.

Starch Degradation

Starch is the major storage form of carbohydrates. During ripening, starch is catabolised into glucose and fructose, which enters the metabolic pool where they are used as respiratory substrates or further converted to other metabolites (Fig. 27.2). In fruits such as banana, the breakdown of starch into simple sugars is associated with fruit softening. There are several enzymes involved in the catabolism of starch. α-amylase hydrolyses amylose molecules by cleaving the α-1,4-linkages between sugars providing smaller chains of amylose termed as dextrins. β-amylase is another enzyme that acts upon the glucan chain releasing maltose, which is a diglucoside. The dextrins as well as maltose can be further catabolised to simple glucose units by the action of glucosidases. Starch phosphorylase is another enzyme, which mediates the phosphorylytic cleavage of terminal glucose units at the non-reducing end of the starch molecule using inorganic phosphate, thus releasing glucose-1-phosphate. The amylopectin molecule is not only degraded in a similar manner to amylose but also involves the action of de-branching

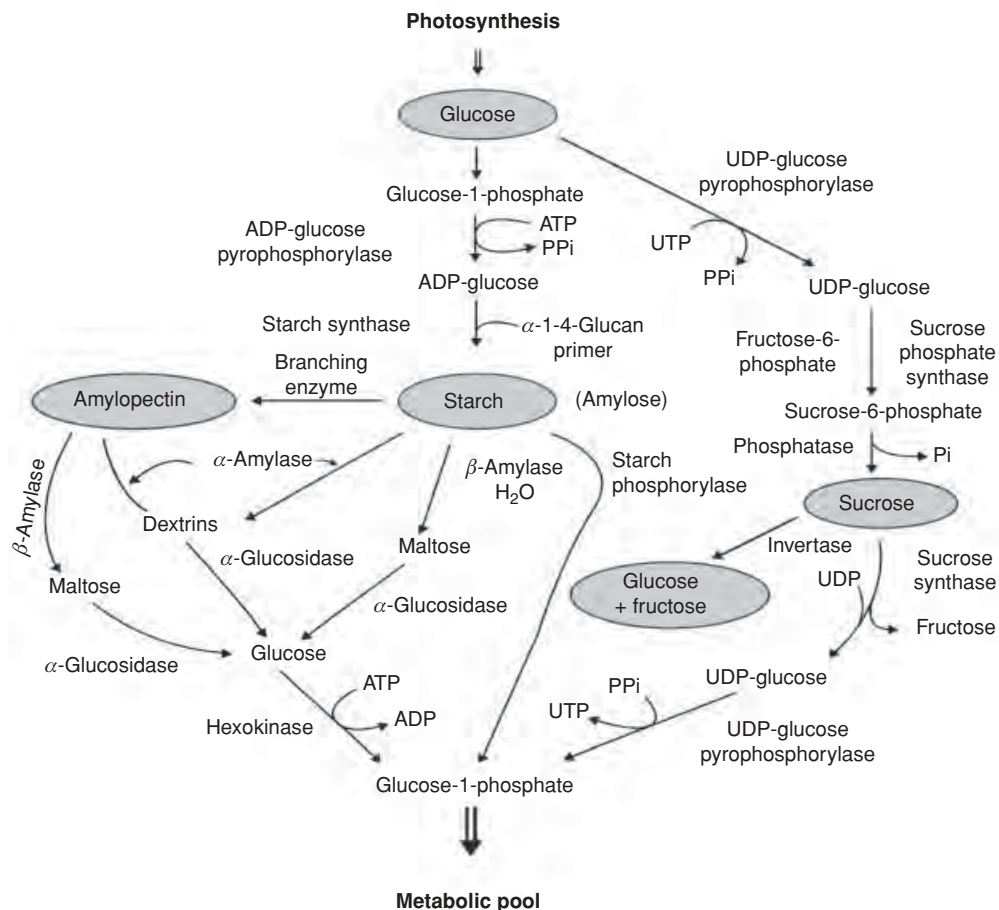
Carbohydrate metabolism in fruits


Figure 27.2. Carbohydrate metabolism in fruits. UDP, Uridine diphosphate; UTP, Uridine triphosphate.

enzymes which cleaves the α-1,6-linkages in amylopectin and releases linear units of the glucan chain.

In general, starch is confined to the plastid compartments of fruit cells, where it exists as granules made up of both amylose and amylopectin molecules. The enzymes that catabolise starch are also found in this compartment and their activities increase during ripening. The glucose-1-phosphate generated by starch degradation (Fig. 27.2) is mobilised into the cytoplasm where it can enter into various metabolic pools such as that of glycolysis (respiration), pentose phosphate pathway (PPP) or for turnover reactions that replenish lost or damaged cellular structures (cell wall components). It is important to visualise that the cell always tries to extend its life under regular developmental conditions (the exceptions being programmed cell death which occurs during hypersensitive response to kill invading pathogens, thus killing both the pathogen and the cell/tissue; formation of xylem vessels, secondary xylem tissues, etc.), and

the turnover reactions are a part of maintaining the homeostasis. The cell ultimately succumbs to the catabolic reactions during senescence. The compartmentalisation and storage of chemical energy in the form of metabolisable macromolecules are all the inherent properties of life, which is defined as a struggle against increasing entropy.

The biosynthesis and catabolism of sucrose is an important part of carbohydrate metabolism. Sucrose is the major form of transport sugar and is translocated through the phloem tissues to other parts of the plant. It is conceivable that carbon dioxide fixed during photosynthesis in leaf tissues may be transported to the fruits as sucrose during fruit development. Sucrose is biosynthesised from glucose-1-phosphate by three major steps (Fig. 27.2). The first reaction involves the conversion of glucose-1-phosphate to UDP-glucose by UDP-glucose pyrophosphorylase in the presence of UTP (Uridine triphosphate). UDP-glucose is also an important substrate for the biosynthesis of

cell wall components such as cellulose. UDP-glucose is converted to sucrose-6-phosphate by the enzyme sucrose phosphate synthase (SPS), which utilises fructose-6-phosphate during this reaction. Finally, sucrose is formed from sucrose-6-phosphate by the action of phosphatase with the liberation of the inorganic phosphate.

Even though sucrose biosynthesis is an integral part of starch metabolism, sucrose often is not the predominant sugar that accumulates in fruits. Sucrose is further converted into glucose and fructose by the action of invertase, which are characteristic to many ripe fruits. By the actions of sucrose synthase and UDP-glucose pyrophosphorylase, glucose-1-phosphate can be regenerated from sucrose. As well, sugar alcohols such as sorbitol and mannitol formed during sugar metabolism are major transport and storage components in apple and olive, respectively.

Biosynthesis and catabolism of starch has been extensively studied in banana, where prior to ripening, it can account for 20–25% by fresh weight of the pulp tissue. All the starch degrading enzymes, α-amylase, β-amylase, α-glucosidase and starch phosphorylase, have been isolated from banana pulp. The activities of these enzymes increase during ripening. Concomitant with the catabolism of starch, there is an accumulation of the sugars, primarily, sucrose, glucose and fructose. At the initiation of ripening, sucrose appears to be the major sugar component, which declines during the advancement of ripening with a simultaneous increase in glucose and fructose through the action of invertase (Beaudry et al. 1989). Mango is another fruit which stores large amounts of starch. The starch is degraded by the activities of amylases during the ripening process. In mango, glucose, fructose and sucrose are the major forms of simple sugars (Selvaraj et al. 1989). The sugar content is generally very high in ripe mangoes and can reach levels in excess of 90% of the total soluble solids content. By contrast to the bananas, the sucrose levels increase with the advancement of ripening in mangoes, potentially due to gluconeogenesis from organic acids (Kumar and Selvaraj 1990). As well, the levels of pentose sugars increase during ripening, and could be related to an increase in the activity of the PPP.

Glycolysis

The conversion of starch to sugars and their subsequent metabolism occur in different compartments. During the development of fruits, photosynthetically fixed carbon is utilised for both respiration and biosynthesis. During this phase, the biosynthetic processes dominate. As the fruit matures and begin to ripen, the pattern of sugar utilisation changes. Ripening is a highly energy-intensive process. And this is reflected in the burst in respiratory carbon dioxide evolution during ripening. As mentioned earlier, the respiratory burst is characteristic of some fruits which are designated as climacteric fruits. The post-harvest shelf life of fruits can depend on their intensity of respiration. Fruits such as mango and banana possess high level of respiratory activity and are highly perishable. The application of controlled atmosphere conditions having low oxygen levels and low temperature have thus become a routine technology for the long-term preservation of fruits.

The sugars and sugar phosphates generated during the catabolism of starch are metabolised through the glycolysis and citric acid cycle (Fig. 27.3). Sugar phosphates can also be channelled through the PPP, which is a major metabolic cycle that provides reducing power for biosynthetic reactions in the form of NADPH, as well as supplying carbon skeletons for the biosynthesis of several secondary plant products. The organic acids stored in the vacuole are metabolised through the functional reversal of respiratory pathway and is termed as gluconeogenesis. Altogether, sugar metabolism is a key biochemical characteristic of the fruits.

In the glycolytic steps of reactions (Fig. 27.3), glucose-6-phosphate is isomerised to fructose-6-phosphate by the enzyme hexose-phosphate isomerase. Glucose 6-phosphate is derived from glucose-1-phosphate by the action of glucose phosphate mutase. Fructose-6-phosphate is phosphorylated at the C1 position, yielding fructose-1,6- bisphosphate. This reaction is catalysed by the enzyme phosphofructokinase (PFK) in the presence of ATP. Fructose-1,6-bisphosphate is further cleaved into two three carbon intermediates, dihydroxyacetone phosphate and glyceraldehyde-3-phosphate, catalysed by the enzyme aldolase. These two compounds are interconvertible through an isomerisation reaction mediated by triose phosphate isomerase. Glyceraldehyde-3-phosphate is subsequently phosphorylated at the C1 position using orthophosphate, as well as oxidised using NAD, to generate 1,3-diphosphoglycerate and NADH. In the next reaction, 1,3-diphosphoglycerate is dephosphorylated by glycerate-3-phosphate kinase in the presence of ADP, along with the formation of ATP. Glycerate-3-phosphate formed during this reaction is further isomerised to 2-phosphoglycerate in the presence of phosphoglycerate mutase. In the presence of the enzyme enolase, 2-phosphoglycerate is converted to phosphoenol pyruvate (PEP). Dephosphorylation of phosphoenolpyruvate in the presence of ADP by pyruvate kinase yields pyruvate and ATP. Metabolic fate of pyruvate is highly regulated. Under normal conditions, it is converted to acetyl CoA, which then enters the citric acid cycle. Under anaerobic conditions, pyruvate can be metabolised to ethanol, which is a by-product in several ripening fruits.

There are two key regulatory steps in glycolysis, one mediated by PFK and the other by pyruvate kinase. In addition, there are other types of modulation involving cofactors and enzyme structural changes reported to be involved in glycolytic control. ATP levels increase during ripening. However, in fruits, this does not cause a feed back inhibition of PFK as observed in animal systems. There are two isozymes of PFK in plants, one localised in plastids and the other localised in the cytoplasm. These isozymes regulate the flow of carbon from the hexose phosphate pool to the pentose phosphate pool. PFK isozymes are strongly inhibited by PEP. Thus, any conditions that may cause the accumulation of PEP will tend to reduce the carbon flow through glycolysis. By contrast, inorganic phosphate is a strong activator of PFK. Thus, the ratio of PEP to inorganic phosphate would appear to be the major factor that regulates the activity of PFK and carbon flux through glycolysis. Structural

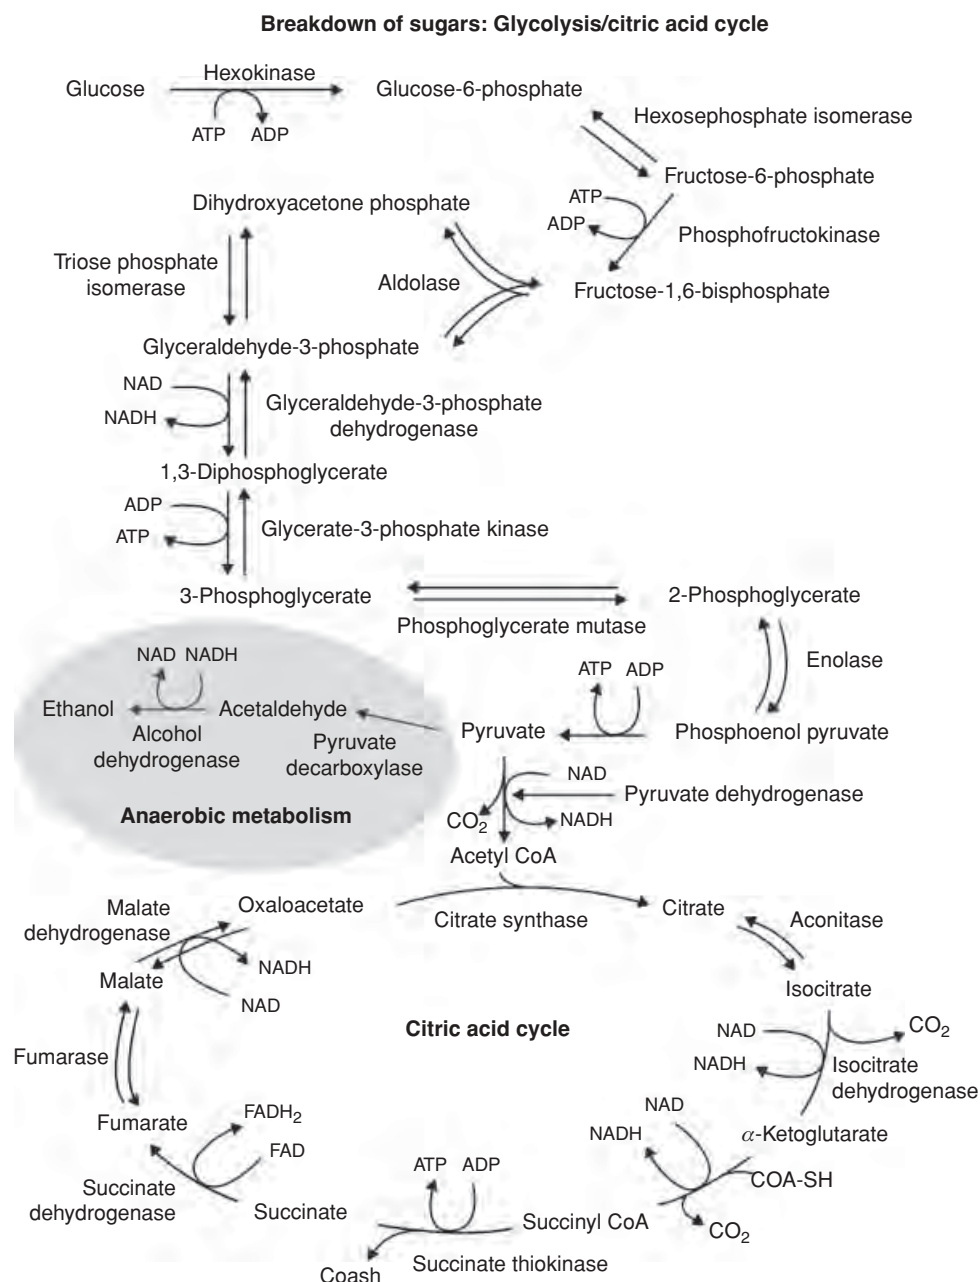
Breakdown of sugars: Glycolysis/citric acid cycle


Figure 27.3. Catabolism of sugars through glycolytic pathway and citric acid cycle.

alteration of PFK, which increases the efficiency of utilisation of fructose-6-phosphate, is another means of regulation that can activate the carbon flow through the glycolytic pathway.

Other enzymes of the glycolytic pathway are involved in the regulation of starch/sucrose biosynthesis (Figs. 27.2 and 27.3). Fructose-1,6-bisphosphate is converted back to fructose-6-phosphate by the enzyme fructose-1,6-bisphosphatase, also releasing inorganic phosphate. This enzyme is localised in the cytosol and chloroplast. Fructose-6-phosphate is converted

to fructose-2,6-bisphosphate by fructose-6-phosphate 2-kinase which can be dephosphorylated at the 2 position by fructose-2,6-bisphosphatase. Fructose-6-phosphate is an intermediary in sucrose biosynthesis (Fig. 27.2). SPS is regulated by reversible phosphorylation (a form of post-translational modification that involves addition of a phosphate moiety from ATP to an OH-amino acid residue in the protein, such as serine or threonine, mediated by a kinase, and dephosphorylation mediated by a phosphatase) by SPS kinase and SPS phosphatase. Phosphorylation

of the enzyme makes it less active. Glucose-6-phosphate is an allosteric activator (a molecule that can bind to an enzyme and increase its activity through enzyme subunit association) of the active form of SPS (dephosphorylated). Glucose-6-phosphate is an inhibitor of SPS kinase and inorganic phosphate is an inhibitor of SPS phosphatase. Thus, under conditions when glucose-6-phosphate/inorganic phosphate ratio is high, the active form of SPS will dominate favouring sucrose phosphate biosynthesis. These regulations are highly complex and may be regulated by the flux of other sugars in several pathways.

The conversion of PEP to pyruvate mediated by pyruvate kinase is another key metabolic step in the glycolytic pathway and is irreversible. Pyruvate is used in several metabolic reactions. During respiration, pyruvate is further converted to acetyl coenzyme A (acetyl CoA), which enters the citric acid cycle through which it is completely oxidised to carbon dioxide (Fig. 27.3). The conversion of pyruvate to acetyl CoA is mediated by the enzyme complex pyruvate dehydrogenase, and is an oxidative step that involves the formation of NADH from NAD. Acetyl CoA is a key metabolite and starting point for several biosynthetic reactions (fatty acids, isoprenoids, phenylpropanoids, etc.).

Citric Acid Cycle

The citric acid cycle involves the biosynthesis of several organic acids, many of which serve as precursors for the biosynthesis of several groups of amino acids. In the first reaction, oxaloacetate combines with acetyl CoA to form citrate, and is mediated by citrate synthase (Fig. 27.3). In the next step, citrate is converted to isocitrate by the action of aconitase. The next two steps in the cycle involve oxidative decarboxylation. The conversion of isocitrate to α-ketoglutarate involves the removal of a carbon dioxide molecule and reduction of NAD to NADH. This step is catalysed by isocitrate dehydrogenase. α-ketoglutarate is converted to succinyl-CoA by α-ketoglutarate dehydrogenase, along with the removal of another molecule of carbon dioxide and the conversion of NAD to NADH. Succinate, the next product, is formed from succinyl CoA by the action of succinyl CoA synthetase that involves the removal of the CoA moiety and the conversion of ADP to ATP. Through these steps, the complete oxidation of the acetyl CoA moiety has been achieved with the removal of two molecules of carbon dioxide. Thus, succinate is a four-carbon organic acid. Succinate is further converted to fumarate and malate in the presence of succinate dehydrogenase and fumarase, respectively. Malate is oxidised to oxaloacetate by the enzyme malate dehydrogenase along with the conversion of NAD to NADH. Oxaloacetate then can combine with another molecule of acetyl CoA to repeat the cycle. The reducing power generated in the form of NADH and FADH (succinate dehydrogenation step) is used for the biosynthesis of ATP through the electron transport chain in the mitochondria.

Gluconeogenesis

Several fruits store large amounts of organic acids in their vacuole and these acids are converted back to sugars during ripening, a process termed as gluconeogenesis. Several irreversible steps in the glycolysis and citric acid cycle are bypassed during gluconeogenesis. Malate and citrate are the major organic acids present in fruits. In fruits such as grapes, where there is a transition from a sour to a sweet stage during ripening, organic acids content declines. Grape contains predominantly tartaric acid along with malate, citrate, succinate, fumarate and several organic acid intermediates of metabolism. The content of organic acids in berries can affect their suitability for processing. High acid content coupled with low sugar content can result in poor-quality wines. External warm growth conditions enhance the metabolism of malic acid in grapes during ripening and could result in a high tartarate/malate ratio, which is considered ideal for vinification.

The metabolism of malate during ripening is mediated by the malic enzyme, NADP-dependent malate dehydrogenase. Along with a decline in malate content, there is a concomitant increase in the sugars, suggesting a possible metabolic precursor product relationship between these two events. Indeed, when grape berries were fed with radiolabelled malate, the radiolabel could be recovered in glucose. The metabolism of malate involves its conversion to oxaloacetate mediated by malate dehydrogenase, the decarboxylation of oxaloacetate to PEP catalysed by PEP-carboxykinase, and a reversal of glycolytic pathway leading to sugar formation (Ruffner et al. 1983). The gluconeogenic pathway from malate may contribute only a small percentage (5%) of the sugars, and a decrease in malate content could primarily result from reduced synthesis and increased catabolism through the citric acid cycle. The inhibition of malate synthesis by the inhibition of the glycolytic pathway could result in increased sugar accumulation. Metabolism of malate in apple fruits is catalysed by NADP-malic enzyme, which converts malate to pyruvate. In apples, malate appears to be primarily oxidised through the citric acid cycle. Organic acids are important components of citrus fruits. Citric acid is the major form of the acid followed by malic acid and several less abundant acids such as acetate, pyruvate, oxalate, glutarate, fumarate and so on. In oranges, the acidity increases during maturation of the fruit and declines during the ripening phase. Lemon fruits, by contrast, increase their acid content through the accumulation of citrate. The citrate levels in various citrus fruits range from 75% to 88%, and malate levels range from 2% to 20%. Ascorbate is another major component of citrus fruits. Ascorbate levels can range from 20 to 60 mg/100 g juice in various citrus fruits. The orange skin may possess 150–340 mg/100 g fresh weight of ascorbate, which may not be extracted into the juice.

Anaerobic Respiration

Anaerobic respiration is a common event in the respiration of ripe fruits and especially becomes significant when fruits are exposed to low temperature. Often, this may result from oxygen-depriving conditions induced inside the fruit. Under anoxia, ATP production through the citric acid cycle and mitochondrial electron transport chain is inhibited. Anaerobic respiration is a means of regenerating NAD, which can drive the glycolyic pathway and produce minimal amounts of ATP (Fig. 27.3). Under anoxia, pyruvate formed through glycolysis

is converted to lactate-by-lactate dehydrogenase using NADH as the reducing factor, and generating NAD. Accumulation of lactate in the cytosol could cause acidification, and under these low pH conditions, lactate dehydrogenase is inhibited. The formation of acetaldehyde by the decarboxylation of pyruvate is stimulated by the activation of pyruvate decarboxylase under low pH conditions in the cytosol. It is also likely that the increase in concentration of pyruvate in the cytoplasm may stimulate pyruvate decarboxylase directly. Acetaldehyde is reduced to ethanol by alcohol dehydrogenase using NADH as the reducing power. Thus, acetaldehyde and ethanol are common volatile components observed in the headspace of fruits indicative of the occurrence of anaerobic respiration. Cytosolic acidification is a condition that stimulates deteriorative reactions. By removing lactate through efflux and converting pyruvate to ethanol, cytosolic acidification can be avoided.

Anaerobic respiration plays a significant role in the respiration of citrus fruits. During early stages of growth, respiratory activity predominantly occurs in the skin tissue. Oxygen uptake by the skin tissue was much higher than the juice vesicles (Purvis 1985). With advancing maturity, a decline in aerobic respiration and an increase in anaerobic respiration was observed in Hamlin orange skin (Bruemmer 1989). In parallel with this, the levels of ethanol and acetaldehyde increased. As well, a decrease in the organic acid substrates pyruvate and oxaloacetate was detectable in Hamlin orange juice. An increase in the activity levels of pyruvate decarboxylase, alcohol dehydrogenase and malic enzyme was noticed in parallel with the decline in pyruvate and accumulation of ethanol. In apple fruits, malic acid is converted to pyruvate by the action of NADP-malic enzyme, and pyruvate subsequently converted to ethanol by the action of pyruvate decarboxylase and alcohol dehydrogenase. The alcohol dehydrogenase in apple can use NADPH as a cofactor, and NADP is regenerated during ethanol production, thus driving malate utilisation. Ethanol is either released as a volatile or can be used for the biosynthesis of ethyl esters of volatiles.

Pentose Phosphate Pathway

Oxidative PPP is a key metabolic pathway that provides reducing power (NADPH) for biosynthetic reactions as well as carbon precursors for the biosynthesis of amino acids, nucleic acids, secondary plant products and so on. The PPP shares many of the sugar phosphate intermediates with the glycolytic pathway (Fig. 27.4). The PPP is characterised by the interconversion of sugar phosphates with three (glyceraldehyde-3-phosphate), four (erythrose-4-phosphate), five (ribulose-, ribose-, xylulose-phosphates), six (glucose-6-phosphate, fructose-6-phosphate) and seven (sedoheptulose-7-phosphate) carbon long chains.

The PPP involves the oxidation of glucose-6-phosphate, and the sugar phosphate intermediates formed are recycled. The first two reactions of PPP are oxidative reactions mediated by the enzymes glucose-6-phosphate dehydrogenase and 6-phosphogluconate dehydrogenase (Fig. 27.4). In the first step, glucose-6-phosphate is converted to 6-phosphogluconate by the removal of two hydrogen atoms by NADP to form NADPH. In the next step, 6-phosphogluconate, a six-carbon sugar acid

phosphate, is converted to ribulose-5-phosphate, a five-carbon sugar phosphate. This reaction involves the removal of a carbon dioxide molecule along with the formation of NADPH. Ribulose-5-phosphate undergoes several metabolic conversions to yield fructose-6-phosphate. Fructose-6-phosphate can then be converted back to glucose-6-phosphate by the enzyme glucose-6-phosphate isomerase and the cycle repeated. Thus, six complete turns of the cycle can result in the complete oxidation of a glucose molecule.

Despite the differences in the reaction sequences, the glycolytic pathway and the PPP intermediates can interact with one another and share common intermediates. Intermediates of both the pathways are localised in plastids, as well as the cytoplasm, and intermediates can be transferred across the plastid membrane into the cytoplasm and back into the chloroplast. Glucose-6-phosphate dehydrogenase is localised both in the chloroplast and cytoplasm. Cytosolic glucose-6-phosphate dehydrogenase activity is strongly inhibited by NADPH. Thus, the ratio of NADP to NADPH could be the regulatory control point for the enzyme function. The chloroplast-localised enzyme is regulated differently through oxidation and reduction, and related to the photosynthetic process. 6-Phosphogluconate dehydrogenase exists as distinct cytosol- and plastid-localised isozymes.

The PPP is a key metabolic pathway related to biosynthetic reactions, antioxidant enzyme function and general stress tolerance of the fruits. Ribose-5-phosphate is used in the biosynthesis of nucleic acids and erythrose-4-phosphate is channelled into phenyl propanoid pathway leading to the biosynthesis of the amino acids phenylalanine and tryptophan. Phenylalanine is the metabolic starting point for the biosynthesis of flavonoids and anthocyanins in fruits. Glyceraldehyde-3-phosphate and pyruvate serve as the precursors for the isoprenoid pathway localised in the chloroplast. Accumulation of sugars in fruits during ripening has been related to the function of PPP. In mangoes, an increase in the levels of pentose sugars observed during ripening has been related to increased activity of PPP. Increases in glucose-6-phosphate dehydrogenase and 6-phosphogluconate dehydrogenase activities were observed during ripening of mango.

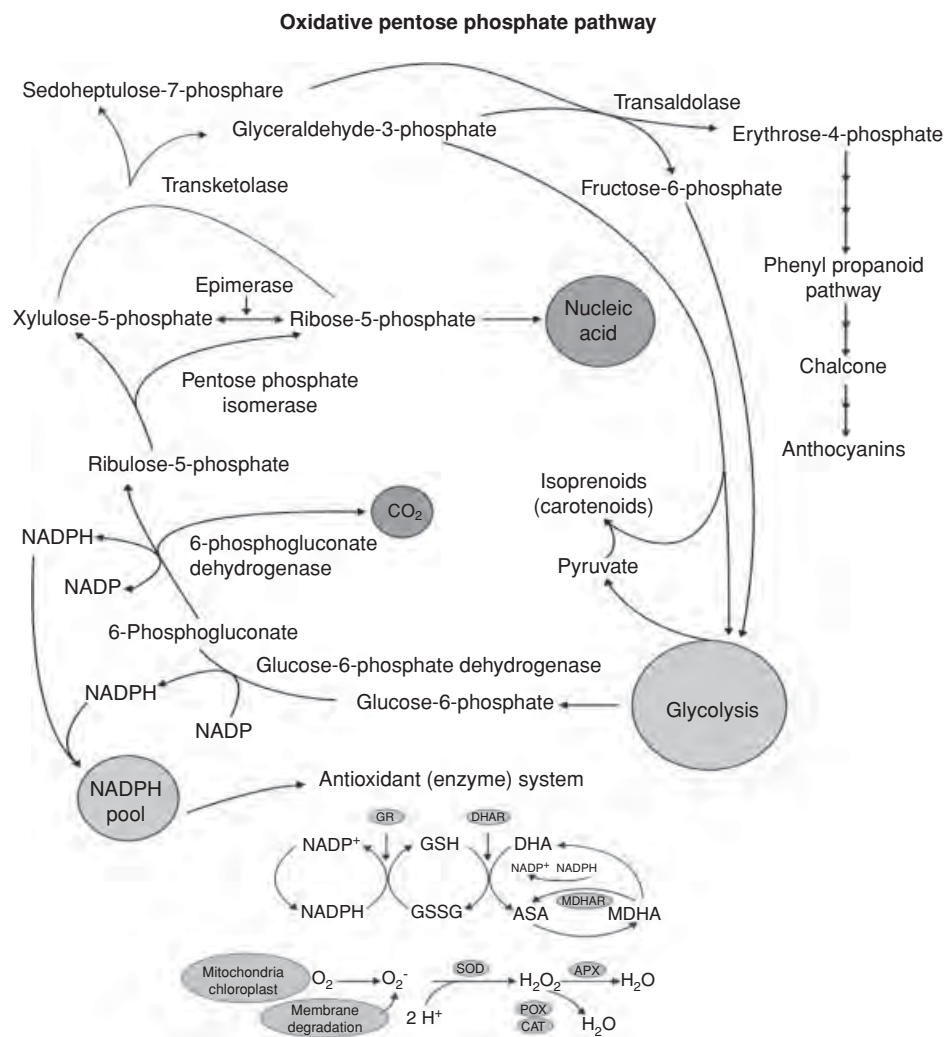
NADPH is a key component required for the proper functioning of the antioxidant enzyme system (Fig. 27.4). During growth, stress conditions, fruit ripening and senescence, free radicals are generated within the cell. Activated forms of oxygen, such as superoxide, hydroxyl and peroxy radicals, can attack enzymes, proteins, nucleic acids and lipids, causing structural and functional alterations of these molecules. Under most conditions, these are deleterious changes, which are nullified by the action of antioxidants and antioxidant enzymes. Simple antioxidants such as ascorbate and vitamin E can scavenge the free radicals and protect the tissue. Anthocyanins and other polyphenols may also serve as simple antioxidants. In addition, the antioxidant enzyme system involves the integrated function of several enzymes. The key antioxidant enzymes are superoxide dismutase (SOD), catalase, ascorbate peroxidase and peroxidase. SOD converts superoxide into hydrogen peroxide. Hydrogen peroxide is immediately acted upon by catalase, generating water. Hydrogen peroxide can also be removed by the action of peroxidases.


Figure 27.4. Oxidative pentose phosphate pathway in plants. NADPH generated from the pentose phosphate pathway is channeled into the antioxidant enzyme system, where the regeneration of oxidised intermediates requires NADPH. GSH, reduced glutathione; GSSG, oxidised glutathione; ASA, reduced ascorbate; MDHA, monodehydroascorbate; DHA, dehydroascorbate; GR, glutathione reductase; DHAR, dehydroascorbate reductase; MDHAR, monodehydroascorbate reductase; SOD, superoxide dismutase; CAT, catalase; POX, peroxidase; APX, ascorbate peroxidase.

A peroxidase uses the oxidation of a substrate molecule (usually having a phenol structure, C–OH, which becomes a quinone, C = O, after the reaction) to react with hydrogen peroxide, converting it to water. Hydrogen peroxide can also be acted upon by ascorbate peroxidase, which uses ascorbate as the hydrogen donor for the reaction, resulting in water formation. The oxidised ascorbate is regenerated by the action of a series of enzymes (Fig. 27.4). These include monodehydroascorbate reductase (MDHAR) and dehydroascorbate reductase (DHAR). Dehydroascorbate is reduced to ascorbate using reduced glutathione (GSH) as a substrate, which itself gets oxidised (GSSG) during this reaction. The oxidised GSH is reduced back to GSH by the activity of GSH reductase using NADPH. Antioxidant

enzymes exist as several functional isozymes with differing activities and kinetic properties in the same tissue. These enzymes are also compartmentalised in chloroplast, mitochondria and cytoplasm. The functioning of the antioxidant enzyme system is crucial to the maintenance of fruit quality through preserving cellular structure and function (Meir and Bramlage 1988, Ahn et al. 2002).

Lipid Metabolism

Among fruits, avocado and olive are the only fruits that significantly store reserves in the form of lipid triglycerides. In avocado, triglycerides form the major part of the neutral lipid

fraction, which can account for nearly 95% of the total lipids. Palmitic (16:0), palmitoleic (16:1), oleic (18:1) and linoleic (18:2) acids are the major fatty acids of triglycerides. The oil content progressively increases during maturation of the fruit, and the oils are compartmentalised in oil bodies or oleosomes. The biosynthesis of fatty acids occurs in the plastids, and the fatty acids are exported into the endoplasmic reticulum where they are esterified with glycerol-3-phosphate by the action of a number of enzymes to form the triglyceride. The triglyceride-enriched regions then are believed to bud off from the endoplasmic reticulum as the oil body. The oil body membranes are different from other cellular membranes, since they are made up of only a single layer of phospholipids. The triglycerides are catabolised by the action of triacylglycerol lipases with the release of fatty acids. The fatty acids are then broken down into acety CoA units through β-oxidation.

Even though phospholipids constitute a small fraction of the lipids in fruits, the degradation of phospholipids is a key factor that controls the progression of senescence. As in several senescing systems, there is a decline in phospholipids as the fruit undergoes senescence. With the decline in phospholipid content, there is a progressive increase in the levels of neutral lipids, primarily diacylglycerols, free fatty acids and fatty aldehydes. In addition, the levels of sterols may also increase. Thus, there is an increase in the ratio of sterol:phospholipids. Such changes in the composition of membrane can cause the formation of gel phase or non-bilayer lipid structures (micelles). These changes can make the membranes leaky, thus resulting in the loss of compartmentalisation, and ultimately, senescence (Paliyath and Droillard 1992).

Membrane lipid degradation occurs by the tandem action of several enzymes, one enzyme acting on the product released by the previous enzyme in the sequence. Phospholipase D (PLD) is the first enzyme of the pathway which initiates phospholipids catabolism and is a key enzyme of the pathway (Fig. 27.6). PLD acts on phospholipids liberating phosphatidic acid and the respective headgroup (choline, ethanolamine, glycerol, inositol). Phosphatidic acid, in turn, is acted upon by phosphatidate phosphatase which removes the phosphate group from phosphatidic acid with the liberation of diacylglycerols (diglycerides). The acyl chains of diacylglycerols are then de-esterified by the enzyme lipolytic acyl hydrolase liberating free fatty acids. Unsaturated fatty acids with a *cis*-1,4- pentadiene structure (linoleic acid, linolenic acid) are acted upon by lipoxygenase (LOX) causing the peroxidation of fatty acids. This step may also cause the production of activated oxygen species such as singlet oxygen, superoxide and peroxy radicals and so on. The peroxidation products of linolenic acid can be 9-hydroperoxy linoleic acid or 13-hydroperoxy linoleic acid. The hydroperoxylinoleic acids undergo cleavage by hydroperoxide lyase resulting in several products including hexanal, hexenal and ω-keto fatty acids (keto group towards the methyl end of the molecule). For example, hydroperoxide lyase action on 13-hydroperoxylinolenic acid results in the formation of *cis*-3-hexenal and 12-keto-cis-9- dodecenoic acid. Hexanal and hexenal are important fruit volatiles. The short-chain fatty acids may feed into catabolic pathway (β-oxidation) that results in the formation of short-chain acyl

CoAs, ranging from acetyl CoA to dodecanoyl CoA. The short-chain acyl CoAs and alcohols (ethanol, propanol, butanol, pentanol, hexanol, etc.) are esterified to form a variety of esters that constitute components of flavour volatiles that are characteristic to fruits. The free fatty acids and their catabolites (fatty aldehydes, fatty alcohols, alkanes, etc.) can accumulate in the membrane causing membrane destabilisation (formation of gel phase, non-bilayer structures, etc.). An interesting regulatory feature of this pathway is the very low substrate specifity of enzymes that act downstream from PLD for the phospholipids. Thus, phosphatidate phosphatase, lipolytic acyl hydrolase and LOX do not directly act on phospholipids, though there are exceptions to this rule. Therefore, the degree of membrane lipid catabolism will be determined by the extent of activation of PLD (Fig. 27.5).

The membrane lipid catabolic pathway is considered as an autocatalytic pathway (Fig. 27.5). The destabilisation of the membrane can cause the leakage of calcium and hydrogen ions from the cell wall space, as well as the inhibition of calcium- and proton ATPases, the enzymes responsible for maintaining a physiological calcium and proton concentration within the cytoplasm (calcium concentration below micromolar range, pH in the 6–6.5 range). Under conditions of normal growth and development, these enzymes pump the extra calcium- and hydrogen ions that enter the cytoplasm from storage areas such as apoplast and the ER lumen in response to hormonal and environmental stimulation using ATP as the energy source. The activities of calcium- and proton ATPases localised on the plasma membrane, the endoplasmic reticulum and the tonoplast are responsible for pumping the ions back into the storage compartments. In fruits (and other senescing systems), with the advancement in ripening and senescence, there is a progressive increase in leakage of calcium and hydrogen ions. PLD is stimulated by low pH and calcium concentration over 10 μM. Thus, if the cytosolic concentrations of these ions progressively increase during ripening or senescence, the membranes are damaged as a consequence. However, this is an inherent feature of the ripening process in fruits, and results in the development of ideal organoleptic qualities that makes them edible. The uncontrolled membrane deterioration can result in the loss of shelf life and quality in fruits (Paliyath et al. 2008).

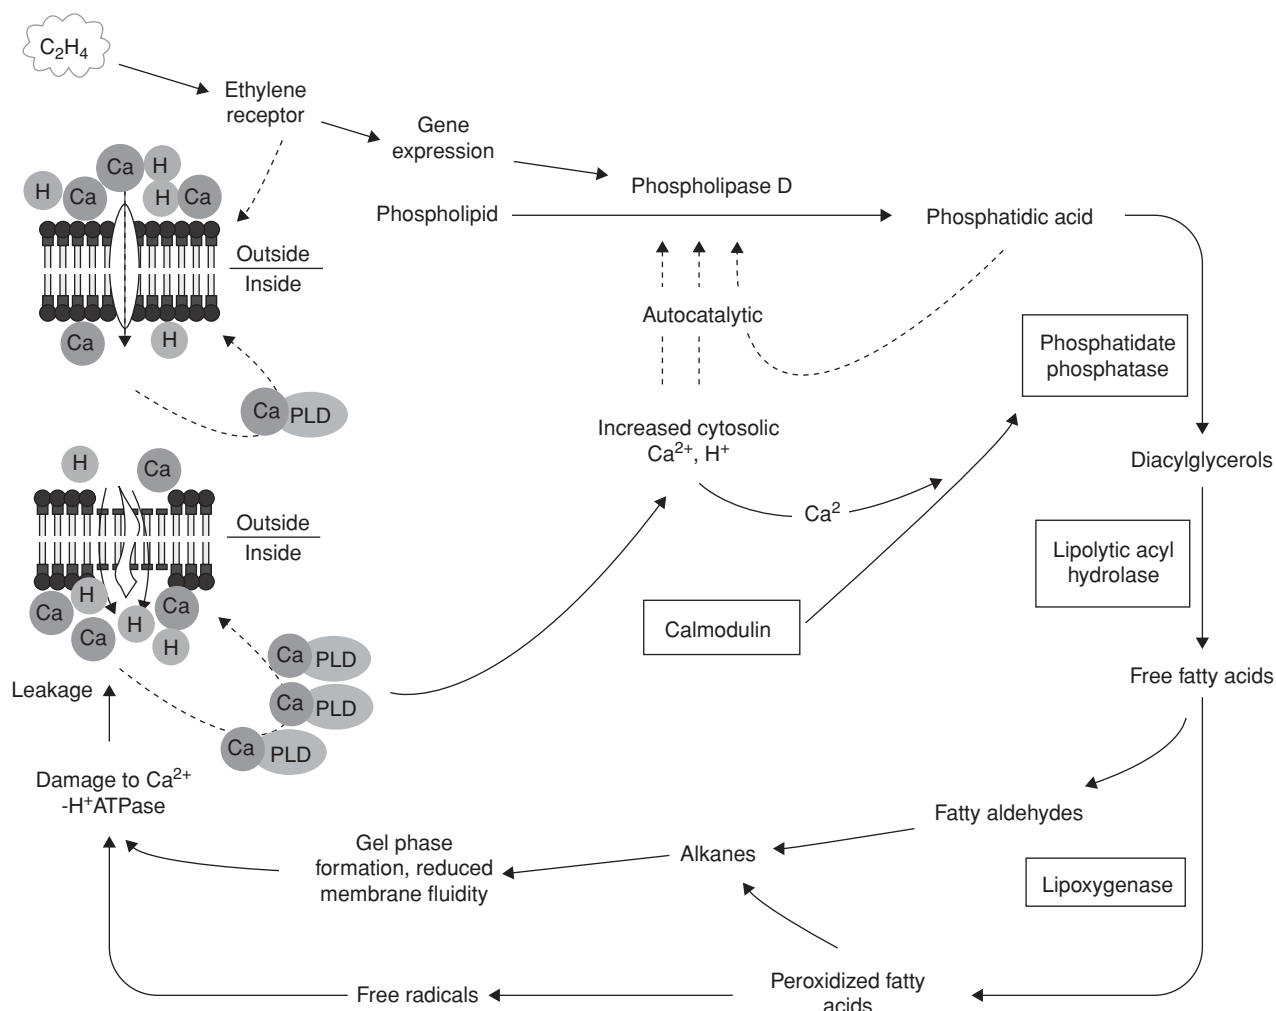
The properties and regulation of the membrane degradation pathway are increasingly becoming clear. Enzymes such as PLD and LOX are very well studied. There are several isoforms of PLD designated as PLD alpha, PLD beta, PLD gamma and so on. The expression and activity levels of PLD alpha are much higher than that of the other PLD isoforms. Thus, PLD alpha is considered as a housekeeping enzyme; however, it is also developmentally regulated (Pinhero et al. 2003). The regulation of PLD activity is an interesting feature. PLD is normally a soluble enzyme. The secondary structure of PLD shows the presence of a segment of around 130 amino acids at the *N*-terminal end, designated as the C2 domain. This domain is characteristic of several enzymes and proteins that are integral components of the hormone signal transduction system. In response to hormonal and environmental stimulation and the resulting increase in cytosolic calcium concentration, C2 domain binds calcium and transports


Figure 27.5. Diagrammatic representation of the autocatalytic pathway of phospholipid degradation that occur during fruit ripening/harvest stress in horticultural produce.

PLD to the membrane where it can initiate membrane lipid degradation. The precise relation between the stimulation of the ethylene receptor and PLD activation is not fully understood, but could involve the release of calcium and migration of PLD to the membrane, formation of a metabolising enzyme complex (metabolon) with other lipid degrading enzymes of the pathway as well as calmodulin. PLD alpha appear to be the key enzyme responsible for the initiation of membrane lipid degradation in tomato fruits (Pinhero et al. 2003). Antisense inhibition of PLD alpha in tomato fruits resulted in the reduction of PLD activity and consequently, an improvement in the shelf life, firmness, soluble solids and lycopene content of the ripe fruits (Whitaker et al. 2001, Pinhero et al. 2003, Oke et al. 2003, Paliyath et al. 2008a). There are other phospholipid degrading enzymes such as phospholipase C and phospholipase A_2. Several roles of these enzymes in signal transduction processes have been extensively reviewed (Wang 2001, Meijer and Munnik 2003).

LOX exists as both soluble and membranous forms in tomato fruits (Todd et al. 1990). Very little information is available on phosphatidate phosphatase and lipolytic acyl hydrolase in fruits.

PROTEOLYSIS AND STRUCTURE BREAKDOWN IN CHLOROPLASTS

The major proteinaceous compartment in fruits is the chloroplast which is distributed in the epidermal and hypodermal layers of fruits. The chloroplasts are not very abundant in fruits. During senescence, the chloroplast structure is gradually disassembled with a decline in chlorophyll levels due to the degradation and disorganisation of the grana lamellar stacks of the chloroplast. With the disorganisation of the thylakoid, globular structures termed as plastoglobuli accumulate within the chloroplast stroma, which are rich in degraded lipids. The degradation of chloroplasts and chlorophyll result in the unmasking of other

coloured pigments and is a prelude to the state of ripening and development of organoleptic qualities. Mitochondria, which are also rich in protein, are relatively stable and undergo disassembly during the latter part of ripening and senescence.

Chlorophyll degradation is initiated by the enzyme chlorophyllase which splits chlorophyll into chlorophyllide and the phytol chain. Phytol chain is made up of isoprenoid units (methyl-1,3-butadiene), and its degradation products accumulate in the plastoglobuli. Flavour components such as 6-methyl-5-heptene-2-one, a characteristic component of tomato flavour, are also produced by the catabolism of phytol chain. The removal of magnesium from chlorophyllide results in the formation of pheophorbide. Pheophorbide, which possesses a tetrapyrrole structure, is converted to a straight chain colourless tetrapyrrole by the action of pheophorbide oxidase. Action of several other enzymes is necessary for the full catabolism of chlorophyll. The protein complexes that organise the chlorophyll, the light-harvesting complexes, are degraded by the action of several proteases. The enzyme ribulose-bis-phosphate carboxylase/oxygenase (Rubisco), the key enzyme in photosynthetic carbon fixation, is the most abundant protein in chloroplast. Rubisco levels also decline during ripening/senescence due to proteolysis. The amino acids resulting from the catabolism of proteins may be translocated to regions where they are needed for biosynthesis. In fruits, they may just enrich the soluble fraction with amino acids.

SECONDARY PLANT PRODUCTS AND FLAVOUR COMPONENTS

Secondary plant products are regarded as metabolites that are derived from primary metabolic intermediates through well-defined biosynthetic pathways. The importance of the secondary plant products to the plant or organ in question may not readily be obvious, but these compounds appear to have a role in the interaction of the plant with the environment. The secondary plant products may include non-protein amino acids, alkaloids, isoprenoid components (terpenes, carotenoids, etc.), flavonoids and anthocyanins, ester volatiles and several other organic compounds with diverse structure. The number and types of secondary plant products are enormous, but, with the perspective of fruit quality, the important secondary plant products include isoprenoids, anthocyanins and ester volatiles.

Isoprenoid Biosynthesis

In general, isoprenoids possess a basic five-carbon skeleton in the form of 2-methyl-1,3-butadiene (isoprene), which undergoes condensation to form larger molecules. There are two distinct pathways for the formation of isoprenoids: the acetate/mevalonate pathway (Bach et al. 1999) localised in the cytosol and the DOXP pathway (Rohmer pathway, Rohmer et al. 1993) localised in the chloroplast (Fig. 27.6). The metabolic precursor for the acetate/mevalonate pathway is acetyl Coenzyme A. Through the condensation of three acetyl CoA molecules, a key component of the pathway, 3-hydroxy-3-methyl-glutaryl CoA (HMG CoA) is generated. HMG-CoA undergoes reduc-

tion in the presence of NADPH mediated by the key regulatory enzyme of the pathway HMG CoA reductase (HMGR), to form mevalonate. Mevalonate undergoes a two-step phosphorylation in the presence of ATP, mediated by kinases, to form isopentenyl pyrophosphate (IPP), the basic five carbon condensational unit of several terpenes. IPP is isomerised to dimethylallylpyrophosphate (DMAPP) mediated by the enzyme IPP isomerase. Condensation of these two components results in the synthesis of C10 (geranyl), C15 (farnesyl) and C20 (geranylgeranyl) pyrophosphates. The C10 pyrophosphates give rise to monoterpenes, C15 pyrophosphates give rise to sesquiterpenes and C20 pyrophosphates give rise to diterpenes. Monoterpenes are major volatile components of fruits. In citrus fruits, these include components such as limonene, myrcene, pinene and so on occurring in various proportions. Derivatives of monoterpenes such as geranial, neral (aldehydes), geraniol, linalool, terpineol (alcohols), geranyl acetate, neryl acetate (esters) and so on are also ingredients of the volatiles of citrus fruits. Citrus fruits are especially rich in monoterpenes and derivatives. Alpha-farnesene is a major sesquiterpene (C15) component evolved by apples. The catabolism of alpha-farnesene in the presence of oxygen into oxidised forms has been implicated as a causative feature in the development of the physiological disorder superficial scald (a type of superficial browning) in certain varieties of apples such as red Delicious, McIntosh, Cortland and so on (Rupasinghe et al. 2000, 2003).

HMGR is a highly conserved enzyme in plants and is encoded by a multigene family (Lichtenthaler et al. 1997). The HMGR genes (*hmg1, hmg2, hmg3*, etc.) are nuclear encoded and can be differentiated from each other by the sequence differences at the 3′-untranslated regions of the cDNAs. There are three distinct genes for HMGR in tomato and two in apples. The different HMGR end products may be localised in different cellular compartments and are synthesised differentially in response to hormones, environmental signals, pathogen infection and so on. In tomato fruits, the level of *hmg1* expression is high during early stage of fruit development when cell division and expansion processes are rapid, when it requires high levels of sterols for incorporation into the expanding membrane compartments. The expression of *hmg2* which is not detectable in young fruits increases during the latter part of fruit maturation and ripening.

HMGR activity can be detected in both membranous and cytosolic fractions of apple fruit skin tissue extract. HMGR is a membrane-localised enzyme, and the activity is detectable in the endoplasmic reticulum, plastid and mitochondrial membranes. It is likely that HMGR may have undergone proteolytic cleavage releasing a fragment into the cytosol, which also possesses enzyme activity. There is a considerable degree of interaction between the different enzymes responsible for the biosynthesis of isoprenoids, which may exist as multienzyme complexes. The enzyme Farnesyl pyrophosphate synthase, responsible for the synthesis of farnesyl pyrophosphate is a cytosolic enzyme. Similarly, farnesene synthase, the enzyme which converts farnesyl pyrophosphate to alpha-farnesene in apples, is a cytosolic enzyme. Thus, several enzymes may act in concert at the cytoplasm/endoplasmic reticulum boundary to synthesise isoprenoids.

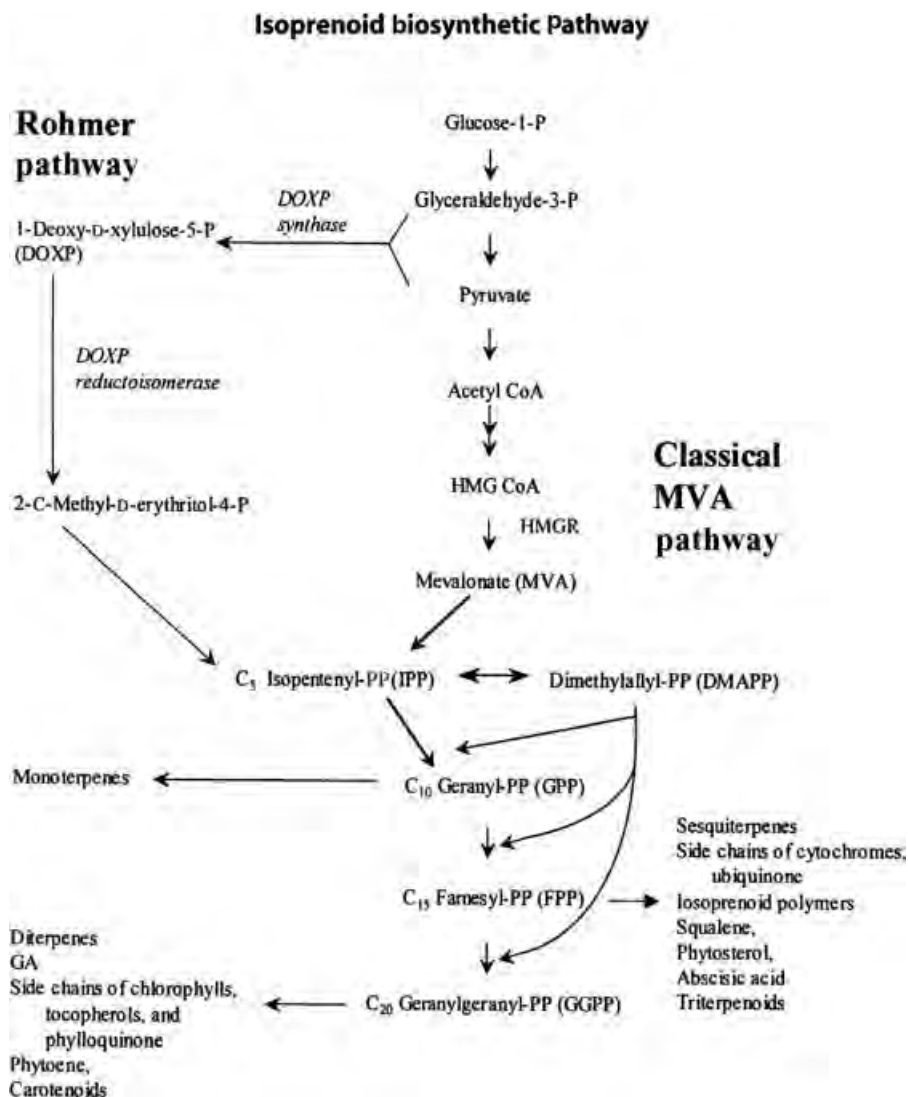
Isoprenoid biosynthetic Pathway


Figure 27.6. Isoprenoid biosynthetic pathway in plants.

HMG CoA reductase expression and activities in apple fruits are hormonally regulated (Rupasinghe et al. 2001, 2003). There are two genes for HMGR in apples designated as *hmg1* and *hmg2*, which are differentially expressed during storage. The expression of *hmg1* was constitutive, and the transcripts (mRNA) were present throughout the storage period. In contrast, the expression of *hmg2* increased during storage in parallel with the accumulation of alpha-farnesene. Ethylene production also increased during storage. Ethylene stimulates the biosynthesis of alpha-farnesene as evident from the inhibition of alpha-farnesene biosynthesis and the expression of *hmg2* by the ethylene action inhibitor 1-methylcyclopropene (MCP). Thus, biosynthesis of isoprenoids is a highly controlled process.

Carotenoids, which are major isoprenoid components of chloroplasts, are biosynthesised through the Rohmer pathway.

The precursors of this pathway are pyruvate and glyceraldehyde-3-phosphate, and through a number of enzymatic steps, 1-deoxy-D-xylulose-5-phosphate (DOXP), a key metabolite of the pathway, is formed. NADPH-mediated reduction of DOXP leads ultimately to the formation of IPP. Subsequent condensation of IPP and DMAPP are similar as in the classical mevalonate pathway. Carotenoids have a stabilising role in the photosynthetic reactions. By virtue of their structure, they can accept and stabilise excess energy absorbed by the light-harvesting complex. During the early stages of fruit development, the carotenoids have primarily photosynthetic function. During fruit ripening, the composition of carotenoids changes to reveal the coloured xanthophylls pigments. In tomato, lycopene is the major carotenoid pigment that accumulates during ripening. Lycopene is an intermediate of the carotene biosynthetic pathway. In young fruits,

lycopene formed by the condensation of two geranylgeranyl pyrophosphate (C20) moieties mediated by the enzyme phytoene synthase is converted to beta-carotene by the action of the enzyme sesquiterpene cyclase. However, as ripening proceeds, the levels and activity of sesquiterpene cyclase are reduced leading to the accumulation of lycopene in the stroma. This leads to the development of red colour in ripe tomato fruits. In yellow tomatoes, the carotene biosynthesis is not inhibited, and as the fruit ripens, the chlorophyll pigments are degraded exposing the yellow carotenoids. Carotenoids are also major components that contribute to the colour of melons. Beta-carotene is the major pigment in melons with an orange flesh. In addition, the contribution to colour is also provided by alpha-carotene, delta-carotene, phytofluene, phytoene, lutein and violaxanthin. In red-fleshed melons, lycopene is the major ingredient, whereas in yellow-fleshed melons, xanthophylls and beta-carotene predominate. Carotenoids provide not only a variety of colour to the fruits but also important nutritional ingredients in human diet. Beta-carotene is converted to vitamin A in the human body and thus serves as a precursor to vitamin A. Carotenoids are strong antioxidants. Lycopene is observed to provide protection from cardiovascular diseases and cancer (Giovanucci 1999). Lutein, a xanthophyll, has been proposed to play a protective role in the retina maintaining the vision and prevention of age-related macular degeneration.

ANTHOCYANIN BIOSYNTHESIS

The development of colour is a characteristic feature of the ripening process, and in several fruits, the colour components are anthocyanins biosynthesised from metabolic precursors. The anthocyanins accumulate in the vacuole of the cell, and are often abundant in the cells closer to the surface of the fruit. Anthocyanin biosynthesis starts by the condensation of three molecules of malonyl CoA with *p*-coumaroyl CoA to form tetrahydroxychalcone, mediated by the enzyme chalcone synthase (Fig. 27.7). Tetrahydroxychalcone has the basic flavonoid structure C6-C3-C6, with two phenyl groups separated by a three-carbon link. Chalcone isomerase enables the ring closure of chalcone leading to the formation of the flavanone, naringenin that possesses a flavonoid structure having two phenyl groups linked together by a heterocyclic ring. The phenyl groups are designated as A and B and the heterocyclic ring is designated as ring C. Subsequent conversions of naringenin by flavonol hydroxylases result in the formation of dihydrokaempferol, dihydromyricetin and dihydroquercetin, which differ in their number of hydroxyl moieties. Dihydroflavonol reductase converts the dihydroflavonols into the colourless anthocyanidin compounds leucocyanidin, leucopelargonidin and leucodelphinidin. Removal of hydrogens and the induction of unsaturation of the C-ring at C2 and C3, mediated by anthocyanin synthase results in the formation of cyanidin, pelargonidin and delphinidin, the coloured compounds (Figs. 27.7 and 27.8). Glycosylation, methylation, coumaroylation and a variety of other additions of the anthocyanidins result in colour stabilisation of the diverse types of anthocyanins seen in fruits. Pelargonidins give orange, pink and red colour, cyanidins provide magenta and crimson colouration, and delphinidins

provide the purple, mauve and blue colour characteristic to several fruits. The colour characteristics of fruits may result from a combination of several forms of anthocyanins existing together, as well as the conditions of pH and ions present in the vacuole.

Anthocyanin pigments cause the diverse colouration of grape cultivars resulting in skin colours varying from translucent, red and black. All the forms of anthocyanins along with those with modifications of the hydroxyl groups are routinely present in the red and dark varieties of grapes. A glucose moiety is attached at the 3 and 5 positions or at both in most grape anthocyanins. The glycosylation pattern can vary between the European (*Vitis vinifera*) and North American (*Vitis labrusca*) grape varieties. Anthocyanin accumulation occurs towards the end of ripening, and is highly influenced by sugar levels, light, temperature, ethylene and increased metabolite translocation from leaves to fruits. All these factors positively influence the anthocyanin levels. Most of the anthocyanin accumulation may be limited to epidermal cell layers and a few of the sub-epidermal cells. In certain high anthocyanin containing varieties, even the interior cells of the fruit may possess high levels of anthocyanins. In the red wine varieties such as merlot, pinot noir and cabernet sauvignon, anthocyanin content may vary between 1500 and 3000 mg/kg fresh weight. In some high-anthocyanin-containing varieties such as Vincent, Lomanto and Colobel, the anthocyanin levels can exceed 9000 mg/kg fresh weight. Anthocyanins are very strong antioxidants and are known to provide protection from the development of cardiovascular diseases and cancer.

Many fruits have a tart taste during early stage of development, which is termed as astringency, and is characteristic to fruits such as banana, kiwi, grape and so on. The astringency is due to the presence of tannins and several other phenolic components in fruits. Tannins are polymers of flavonoids such as catechin and epicatechin, phenolic acids (caffeoyl tartaric acid, coumaroyl tartaric acid, etc.). The contents of tannins decrease during ripening, making the fruit palatable.

ESTER VOLATILE BIOSYNTHESIS

The sweet aroma characteristic to several ripe fruits are due to the evolution of several types of volatile components that include monoterpenes, esters, organic acids, aldehydes, ketones, alkanes and so on. Some of these ingredients specifically provide the aroma characteristic to fruits and are referred to as character impact compounds. For instance, the banana flavour is predominantly from isoamyl acetate, apple flavour from ethyl-2 methyl butyrate, and the flavour of lime is primarily due to the monoterpene limonene. As the name implies, ester volatiles are formed from an alcohol and an organic acid through the formation of an ester linkage. The alcohols and acids are, in general, products of lipid catabolism. Several volatiles are esterified with ethanol giving rise to ethyl derivatives of aliphatic acids (ethyl acetate, ethyl butyrate, etc.).

The ester volatiles are formed by the activity of the enzyme Acyl CoA: alcohol acyltransferase or generally called as alcoholacyltransferase (AAT). In apple fruits, the major aroma components are ester volatiles (Paliyath et al. 1997). The alcohol can vary from ethanol, propanol, butanol, pentanol, hexanol and

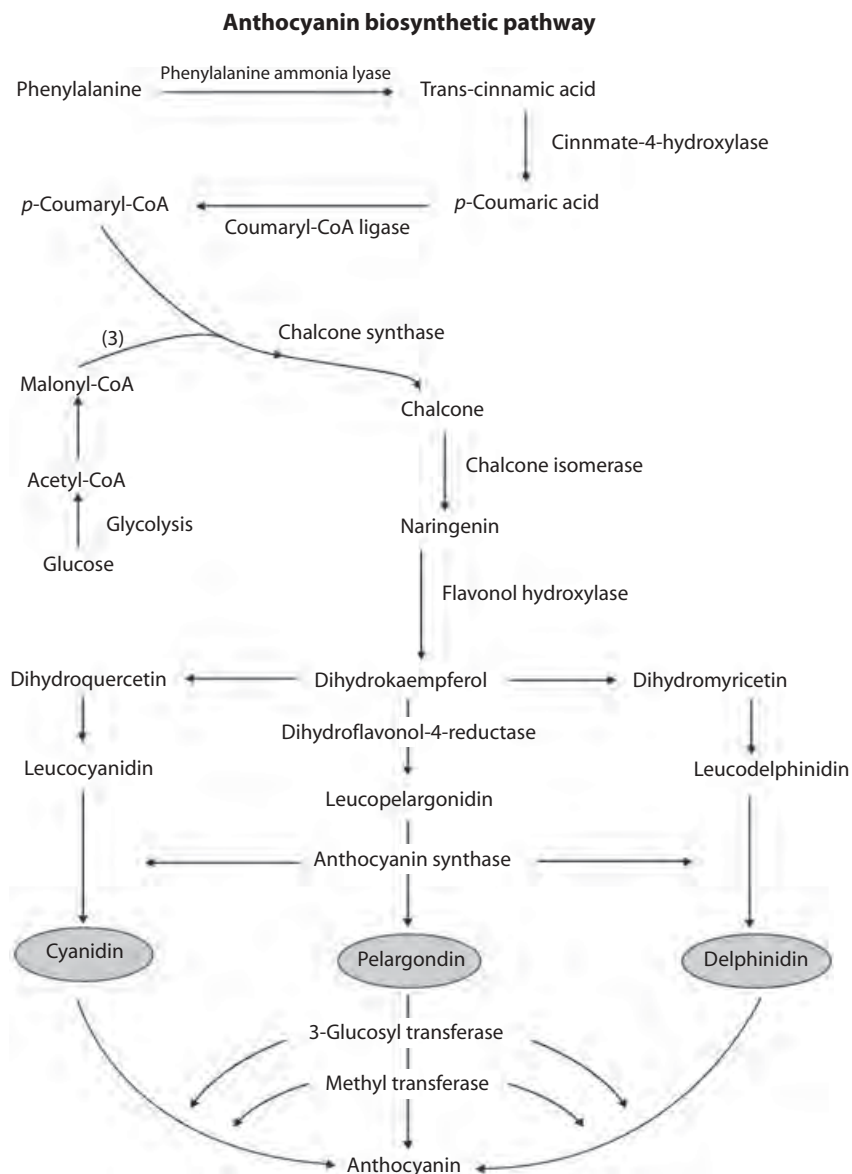
Anthocyanin biosynthetic pathway


Figure 27.7. Anthocyanin biosynthetic pathway in plants.

so on. The organic acid moiety containing the CoA group can vary in chain length from C2 (acetyl) to C12 (dodecanoyl). AAT activity has been identified in several fruits that include banana, strawberry, melon, apple and so on. In banana, esters are the predominant volatiles enriched with esters such as acetates and butyrates. The flavour may result from the combined perception of amyl esters and butyl esters. Volatile production increases during ripening. The components for volatile biosynthesis may arise from amino acids and fatty acids. In melons, the volatile components comprise esters, aldehydes, alcohols, terpenes and lactones. Hexyl acetate, isoamyl acetate and octyl acetate are the major aliphatic esters. Benzyl acetate, phenyl propyl acetate and

phenyl ethyl acetate are also observed. The aldehydes, alcohols, terpenes and lactones are minor components in melons. In mango fruits, the characteristic aroma of each variety is based on the composition of volatiles. The variety "Baladi" is characterised by the presence of high levels of limonene, other monoterpenes and sesquiterpenes, and ethyl esters of even numbered fatty acids. By contrast, the variety "Alphonso" is characterised by high levels of C6 aldehydes and alcohols (hexanal, hexanol) that may indicate a high level of fatty acid peroxidation in ripe fruits. C6 aldehydes are major flavour components of tomato fruits as well. In genetically transformed tomatoes (antisense PLD), the evolution of pentanal and hexenal/hexanal was much higher

Antho cyanidins
Figure 27.8. Some common anthocyanidins found in fruits and flowers.

after blending, suggesting the preservation of fatty acids in ripe fruits. Preserving the integrity of the membrane during ripening could help preserve the fatty acids that contribute to the flavour profile of the fruits and this feature may provide a better flavour profile for fruits.

Biochemistry of Fruit Processing

Moustapha Oke, Jissy K. Jacob, and Gopinadhan Paliyath

Abstract: Processing of fruits is an important segment of food industry. As fruits are highly perishable, processing is an efficient way of ensuring their year-round availability. Fruits are processed into juice, sauce, infused and dried products. Several standardized techniques are available to preserve the quality of processed products, still, there are nutrient losses associated with processing. Common fruits processed include grape, orange, apples, pears, peach, and so on. Processed fruits can be enriched with the addition of nutraceutical components.

INTRODUCTION

Overall, the food and beverage processing industry is an important manufacturing sector all across the world. The United States is among the top producers and consumers of fruits and tree nuts in the world. Each year, fruit and tree nut production generates about 13% of US farm cash receipts for all agricultural crops. Annual US per capita use of fruit and tree nuts totals nearly 300 pounds fresh-weight equivalent. Oranges, apples, grapes, and bananas are the most popular fruits. The consumption of fruits and processed products has enjoyed an unprecedented growth during the past decade. Many factors motivate this increase, including consumers' awareness of the health benefits of fruit constituents such as the importance of dietary fiber, antioxidants, vitamins, minerals, and phytochemicals present in fruits. In food stores, one can buy fresh and processed exotic food items, either canned, frozen, dehydrated, fermented, pickled, or made into jams, jellies, and marmalades year-round. Several varieties of fruits are sold throughout the year in developed countries, and with the increase in international trade of fruits, even tropical fruits are available at a reasonable cost. The food processing industry uses fruits as ingredients in juice blends, snacks, baby foods, and many other processed food items. As a

Table 28.1. World Production of Fruit in 2002 in Metric Tons

Production (Metric Tons)	Africa	Asia	Europe	America	Australia and New Zealand	World
Primary fruits	61,934,001	204,640,809	73,435,847	129,642,621	4,438,090	475,503,880
Apples	1,696,109	30,870,497	15,820,454	7,875,880	831,999	57,094,939
Bananas	7,140,629	35,766,134	446,600	15,372,622	250,000	69,832,378
Grapes	3,113,940	14,761,974	28,739,848	12,529,900	1,872,588	61,018,250
Mangoes	2,535,781	19,841,469	–	3,343,697	28,000	25,748,947
Oranges	4,920,544	14,177,590	6,180,846	38,402,953	444,500	64,128,523
Pears	530,547	10,996,503	3,626,020	1,759,538	202,597	17,115,205
Plums	173,946	5,385,634	2,661,194	1,069,953	24,000	9,314,727
Strawberries	171,132	325,670	1,276,192	1,157,540	21,300	3,237,533

Source: Calculated from FAOSTAT database. http://faostat.fao.org/default.aspx. Accessed on December 07, 2011.

result, the world production of primary fruits has increased from 384 million metric tons in 1992 to 475 million metric tons in 2002 (FAO). The world production of fruits in 2002 by regions is shown in Table 28.1.

Advances in fruit processing technologies mostly occur in response to consumer demands or improvement in the efficiency of technology. Traditional methods of canning, freezing, and dehydration are progressively being replaced by fresh-cut, ready-to-eat fruit preparations. The use of modified atmosphere and irradiation also helps in extending the shelf life of produce.

Fruits are essential source of minerals, vitamins, and dietary fiber. In addition to these components, they provide carbohydrates, and to a lesser extent, proteins. Fruits play an important role in the digestion of meat, cheese, and other high-energy foods by neutralizing the acids produced by the hydrolysis of lipids.

FRUIT CLASSIFICATION

Fruits can be broadly grouped into three categories according to their growth latitude, whether it is in temperate, subtropical, or tropical regions.

1. *Temperate zone fruits*: Four subgroups can be distinguished among temperate zone fruits that include small fruits and berries (e.g., grape, strawberry, blueberry, blackberry, cranberry), stone fruits (e.g., peach, plum, cherry, apricot, nectarine) and pome fruits, (e.g., apple, pear, Asian pear or Nashi, and European pear or quince).
2. *Subtropical fruits*: Two subgroups can be differentiated among subtropical fruits and include citrus fruits (e.g., orange, grapefruit, lemon, tangerine, mandarin, lime, and pummelo), and noncitrus fruits (e.g., avocado, fig, kiwifruit, olive, pomegranate, and cherimoya).
3. *Tropical fruits*: Major tropical fruits include banana, mango, papaya, and pineapple. Minor tropical fruit include passion fruit, cashew apple, guava, longan, lychee, mangosteen, carambola, rambutan, sapota, and so on.

CHEMICAL COMPOSITION OF FRUITS

CARBOHYDRATES

Fruits typically contain between 10% and 25% carbohydrates, less than 1% of protein and less than 0.5% of fat (Somogyi et al. 1996b). Carbohydrates, sugars, and starches are broken down into CO_2, water, and energy during catabolism. The major sources of carbohydrates are banana, plantain, date, raisin, breadfruit, and jackfruit. Proteins and amino acids are contained in dried apricot and fig, whereas fats are the major components of avocado and olives. Sugars are the major carbohydrate components of fruits and their composition vary from fruit to fruit. In general, sucrose, glucose, and fructose are the major sugar components present in fruits (Table 28.2). Several fruits also contain sugar alcohols such as sorbitol.

VITAMINS

Fruits and vegetables are major contributors to our daily vitamin requirements. The nutrient contribution from a specific fruit or vegetable is dependent on the amount of vitamins present in the fruit or vegetable, as well as the amount consumed. The approximate percentage contribution to daily vitamin intake from fruits and vegetables is: vitamin A, 50%; thiamine, 60%; riboflavin, 30%; niacin, 50%; and vitamin C, 100% (Somogyi et al. 1996b). Vitamins are sensitive to different processing conditions such as exposure to heat, cold, reduced and high levels of oxygen, light, free water, and mineral ions. Trimming, washing, blanching, and canning can also cause the loss in vitamin content of fruits and vegetables.

MINERALS

Minerals found in fruits in general may not be fully nutritionally available (e.g., calcium, found as calcium oxalate in certain produce is not nutritionally available). Major minerals in fruits are base-forming elements (K, Ca, Mg, Na) and acid-forming elements (P, Cl, S). Minerals often present in microquantities are Mn, Zn, Fe, Cu, Co, Mo, and I. Potassium is the most abundant mineral in fruits, followed by calcium and magnesium. High potassium is often associated with increased acidity and

Table 28.2. Sugar Composition of Selected Fruits

	Sugar, g/100 mL of Juice			
Fruit	Sucrose	Glucose	Fructose	Sorbitol
Apple	0.82±0.13	2.14±0.43	5.31±0.94	0.20±0.04
Cherry	0.08±0.02	7.50±0.81	6.83±0.74	2.95±0.33
Grape	0.29±0.08	9.59±1.03	10.53±1.04	ND
Nectarine	8.38±0.73	0.85±0.04	0.59±0.02	0.27±0.04
Peach	5.68±0.52	0.67±0.06	0.49±0.01	0.09±0.02
Pear	0.55±0.12	1.68±0.36	8.12±1.56	4.08±0.79
Plum	0.51±0.36	4.28±1.18	4.86±1.30	6.29±1.97

ND, not detected (<0.05 g/100 mL).

improved color, whereas high calcium content reduces the incidence of physiological disorders and improves quality of fruits. Phosphorus is a constituent of several metabolites and nucleic acids and plays an important role in carbohydrate metabolism and energy transfer.

DIETARY FIBER

Dietary fiber consists of cellulose, hemicellulose, lignin, and pectic substances, which are derived from fruit cell walls and skins. The dietary fiber content of fruits ranges from 0.5% to 1.5% by fresh weight. Because of its properties that include a high water-holding capacity, dietary fiber plays a major role in the movement of digested food and reducing the incidence of colon cancer and cardiovascular disease.

PROTEINS

Fruits contain less than 1% protein (as opposed to 9–20% protein in nuts). In general, plant protein sources provide a significant portion of dietary protein requirement in countries where animal proteins are in short supply. Plant proteins, unlike animal proteins, are often deficient or limiting in one or more essential amino acids. The green fruits are important sources of proteins as they contain enzymes and proteins associated with the photosynthetic apparatus. Enzymes, which catalyze metabolic processes in fruits, are important in the reactions involved in fruit ripening and senescence. Some of the enzymes important to fruit quality are:

- *Ascorbic acid oxidase*: Catalyzes oxidation of ascorbic acid and results in loss of nutritional quality.
- *Chlorophyllase*: Catalyzes removal of phytol ring from chlorophyll; results in loss of green color.
- *Polyphenol oxidase*: Catalyzes oxidation of phenolics, resulting in the formation of brown colored polymers.
- *Lipoxygenase*: Catalyzes oxidation of unsaturated fatty acids; results in off-odor and off-flavor production.

- *Polygalacturonase*: Catalyzes hydrolysis of glycosidic bonds between adjacent polygalacturonic acid residues in pectin; results in tissue softening.
- *Pectinesterase*: Catalyzes deesterification of methyl groups in pectin; Act in conjunction with polygalacturonases, leading to tissue softening.
- *Cellulase*: Catalyzes hydrolysis of cellulose polymers in the cell wall and therefore is involved in fruit softening.
- *Phospholipase D*: Initiates the degradation of cell membrane.

LIPIDS

In general, the lipid content of fruits is very small amounting to 0.1–0.2%. Avocado, olive, and nuts are exceptions. Despite the relatively small amount of storage lipids in fresh fruits, they still possess cell membrane lipids. Lipids make up the surface wax, which contributes to the shiny appearance of fruits, and cuticle, which protects fruits against water loss and pathogens. The degree of fatty acid saturation establishes membrane fluidity with greater saturation, resulting in less fluidity. Lipids play a significant role in the characteristic aroma and flavor of fruits. For example, the characteristic aroma and flavor of cut fruits result from the action of the enzyme lipoxygenase on fatty acids (linoleic and linolenic acids), eventually leading to the production of volatile compounds. The action of lipoxygenase is increased after the fruit is cut because there is a greater chance for the enzyme and substrate to mix together. Lipoxygenase can also be responsible for the off-flavor and off-aroma in certain plant products (soybean oil).

VOLATILES

The specific aroma of fruits is due to the amount and diversity of volatiles they contain. Volatiles are present in extremely small quantities (<100 ug/g fresh wt). Ethylene is the most abundant volatile in fruit, but has no typical fruit aroma. Characteristic flavors and aromas are a combination of various character impact compounds, mainly esters, terpenes, short chain aldehydes,

Table 28.3. Organic Acids of Selected Fruits

| Fruit | Organic Acid, mg/100 mL of Juice | | | | |
	Citric	Ascorbic	Malic	Quinic	Tartaric

ND, not detected; Tr, <10 mg/100 mL.

ketones, organic acids, and so on. Their relative importance depends upon the threshold concentration (sometimes, <1 ppb) and interaction with other compounds. For some fruits such as apple and bananas, the specific aroma is determined by the presence of a single compound, ethyl-2-methylbutyrate in apples, and isoamylacetate in bananas.

WATER

Water is the most abundant single component of fruits and vegetables (up to 90% of total weight). The maximum water content of fruits varies due to structural differences. Agricultural conditions also influence the water content of plants. As a major component of fruits, water has an impact on both the quality and the deterioration. Turgidity is a major quality determinant factor in fruits. Loss of turgor is associated with loss of quality, and is a major problem during postharvest storage and transportation. Harvest should be done during the cool part of the day in order to keep the turgidity at its optimum.

ORGANIC ACIDS

The role of organic acids in fruits is twofold.

1. Organic acids are an integral part of many metabolic pathways, especially Krebs (TCA) cycle. Tricarboxylic acid cycle (respiration) is the main channel for the oxidation of organic acids, serving as an important energy source for the cells. Organic acids are metabolized into many constituents including amino acids. Major organic acids present in fruits include citric acid, malic acid, and quinic acid.
2. Organic acids are important contributors to the taste and flavor of many fruits and vegetables. Total titratable acidity, the quantity and specificity of organic acids present in fruits and so one influence the buffering system and the pH. Acid content decreases during ripening, because part of it is used for respiration and another part is transformed

into sugars (gluconeogenesis). The composition of organic acids in some fruits is given in (Table 28.3).

PIGMENTS

Pigments are mainly responsible for the skin and flesh colors in fruits and vegetables. They undergo changes during maturation and ripening of the fruits including, loss of chlorophyll (green color), synthesis and/or revelation of carotenoids (yellow and orange), and biosynthesis of anthocyanins (red, blue, and purple) (Table 28.4.). Anthocyanins occur as glycosides and are water soluble, unstable, and easily hydrolyzed by enzymes to free

Table 28.4. Anthocyanins of Selected Fruits

| Fruit | Anthocyanin | |
	Identification	Peak Area
Apple	Cyanidin 3-arabinoside	22±6
	Cyanidin 7-arabinoside or Cyanidin 3-glucoside	27±15
	Cyanidin 3-galactoside	260±69
Cherry	Cyanidin 3-glucoside	189±40
	Cyanidin 3-rutinoside	1320±109
	Peonidin 3 rutinoside	47±36
Grape	Cyanidin 3-glucoside	121±33
	Delphinidin 3-glucoside	586±110
	Malvidin 3-glucoside	2157±375
	Peonidin 3-glucoside	478±92
Nectarine	Cyanidin 3-glucoside	322±51
Peach	Cyanidin 3-glucoside	180±43
Plum	Cyanidin 3-glucoside	42±5
Strawberry	Cyanidin 3-glucoside	70±18
	Pelargonidin 3-glucoside	1302±29
	Pelargonidin 3-glycoside	78±9

anthocyanins. The latter may be oxidized to brown products by phenoloxidases after wounding.

PHENOLICS

Fruit phenolics include chlorogenic acid, catechin, epicatechin, leucoanthocyanidins and anthocyanins, flavonoids, cinnamic acid derivatives, and simple phenols. The total phenolic content of fruits varies from 1 to 2 g/100 g fresh weight. Chlorogenic acid is the main substrate responsible for the enzymatic browning of damaged fruit tissue. Phenolic components are oxidized by polyphenol oxidase enzyme in the presence of O_2 to brown products according to the following reactions.

$$\text{Monophenol} + O_2 \xrightarrow{\text{Polyphenol oxidase}} \text{quinone} + H_2O$$
$$\text{1,4 diphenol} + O_2 \xrightarrow{\text{Polyphenol oxidase}} \text{1,4 quinone} + H_2O$$
Phenolic components are responsible for the astringency in fruits and decrease with maturity because of their conversion from soluble to insoluble forms, and metabolic conversions.

CELL STRUCTURE

The fruit is composed of three kinds of cells that include parenchyma, collenchyma, and sclerenchyma.

1. *Parenchyma cells*: Parenchyma cells are the most abundant cells found in fruits. These cells are mostly responsible for the texture resulting from turgor pressure.
2. *Collenchyma cells*: Collenchyma cells contribute to the plasticity of fruit material. The collenchyma cells are located usually closer to the periphery of fruits. Collenchyma cells have thickened lignified cell walls and are elongated in their form.
3. *Sclerenchyma cells*: Also called stone cells, for example, in pears, sclerenchyma cells are responsible for the gritty/sandy texture of pears. They have very thick lignified cell walls and are also responsible for the stringy texture in such commodities as asparagus. For some commodities such as asparagus, the number of sclerenchyma cells increases after harvest and during handling, and storage.

FRUIT PROCESSING

HARVESTING AND PROCESSING OF FRUITS

Harvesting is one of the most important of fruit-growing activities. It represents about half of the cost involved in fruit production because most fruit crops are still harvested by hand. Improvement needs to be done for the development of mechanical harvesters. Production of fruits of nearly equal size, and resistant to mechanical damage during harvest, is another area addressed by breeding technology. Certain fruits that are not to be processed are harvested with stems in order to avoid microbial invasion. Examples of this include cherries and apples.

Harvested fruit is washed to remove soil, microorganisms and pesticide residues, and then sorted according to their size and quality. Fruit sorting can be done by hand or mechanically. There are two ways of mechanical sorting of fruits, sorting with water, which takes advantage of changes in density with ripening; and automatic high-speed sorting, in which compressed air jets separate fruit in response to differences in color and ripeness as measured by light reflectance or transmittance. When not marketed as fresh, fruits are processed in many ways including: canning, freezing, concentration, and drying.

FREEZING AND CANNING OF FRUITS

For freezing and canning of fruits, the general sequence of operations includes (1) washing; (2) peeling; (3) cutting, trimming, coring; (4) blanching; (5) packaging and sealing; and (6) heat processing or freezing.

Freezing is generally superior to canning for preserving the firmness of fruits. In order to minimize postharvest changes, freezing process is done at the harvest site for certain fruits. Fruit to be frozen must be stabilized against enzymatic changes during frozen storage and on thawing. The principal enzymatic changes are oxidations, causing darkening of color and the production of off-flavor. An important color change is enzymatic browning in apples, peaches, and bananas. This is due to the oxidation of pigment precursors such as *o*-diphenols and tannins by enzymes of the group known as phenol oxidases and polyphenol oxidases. Frozen fruits are produced for home use, restaurants, baking manufacturers, and other food industries. Depending on the intended end use, various techniques are employed to prevent oxidation.

The objective of blanching is to inhibit various enzyme reactions that reduce the quality of fruits. Fruits generally are not heat blanched because the heat causes loss of turgor, resulting in sogginess and juice drainage after thawing. An exception to this is when the frozen fruit is to receive heating during the baking operation, in which case calcium salts are added to the blanching water or after blanching. Calcium salts increase the firmness of the fruit by forming calcium pectates. For the same purpose, pectin, carboxymethyl cellulose, alginates, and other colloidal thickeners can also be added to fruit prior to freezing. Instead of heat treatments, certain chemicals can be used in order to inactivate oxidative enzymes or to act as antioxidants. The major antioxidant treatments include ascorbic acid dip and treatment with sulfites. Other methods for the prevention of contact with oxygen using physical barriers (sugar syrup) can be used.

Commonly dissolved in sugar syrup, vitamin C acts as an antioxidant and protects the fruit from darkening by subjecting itself to oxidation. A concentration of 0.05–0.2% ascorbic acid in syrup is effective for apple and peach. Peaches subjected to this treatment may not darken during frozen storage at $-18°C$ for up to 2 years. Because low pH also helps in delaying oxidative processes, vitamin C and citric acid may be used in combination. Furthermore, citric acid removes cofactors of oxidative enzymes such as copper ions in polyphenol oxidase.

Sulfite is a multiple function antioxidant. Bisulfites of sodium or calcium are used to stabilize the color of fresh fruits. Like vitamin C, sulfite is an oxygen acceptor and inhibits the activity of oxidizing enzymes. Furthermore, sulfite reduces the

nonenzymatic Maillard-type browning reactions by reacting with aldehyde groups of sugars so that they are no longer free to combine with amino acids. Inhibition of browning is especially important in dried fruits such as apples, apricots, and pears. Sulfite also exhibits antimicrobial properties. The disadvantage of sulfite is that some people are allergic to this chemical, which makes its use restricted, for example, FDA prohibited the use of sulfite in fresh produce and limited the residual in processed products to 10 ppm, with appropriate label.

Sugar syrup has long been used to minimize oxidation before the mechanisms of browning reactions were understood, and still remains as a common practice today. Application of sugar syrup provides a coating to the fruit and thus prevents the contact of the cut surface and oxidizable components from contact with atmospheric oxygen. Sugar syrup also increases the sensory attributes of fruits, by reducing the loss of volatiles and improving the taste.

Vacuum treatment is used in combination with the chemical dips in order to improve their effects. While fruits are submerged in the dip, vacuum is applied to draw air from the fruit tissue, allowing better penetration.

In order to reduce the cost of handling and shipping, some high-moisture fruits are pureed and concentrated to two or three times their natural solids content. Many others are dried for various purposes to different moisture levels. The majority of fruit including apricot, apple, figs, pears, prunes, and raisins are sun dried. Sulfite is commonly used to preserve the color when fruits are dried under high temperature that does not inactivate the oxidative enzymes.

NONENZYMATIC BROWNING

Also called Maillard reaction, the nonenzymatic browning is of great importance in fruit processing. During Maillard reaction, the amino groups of amino acids, peptides, or proteins, react with aldehyde groups of sugars resulting in the formation of brown nitrogenous polymers called melanoidins (Ellis 1959, deMan 1999). The velocity and pattern of the reaction depend on the nature of the reacting compounds, the pH of the medium, and the temperature. Each kind of food shows a different browning pattern. Lysine is the most reactive amino acid because it contains a free amino group. The destruction of lysine reduces the nutritional value of a food since it is a limiting essential amino acid. The major steps involved in the Maillard reaction are:

1. An aldose or ketose reacts with a primary amino group of amino acid, peptide or protein, to produce an *N*-substituted glycosylamine;
2. The Amadori reaction, which rearranges the glycosylamine to yield ketosamine or aldoseamine;
3. Rearrangement of the ketosamine with a second molecule of aldose to yield diketosamine, whereas the rearrangement of the aldoseamine with a second molecule of amino acid leads to a diamino sugar;
4. Amino sugars are degraded by losing water to give rise to amino or nonamino compounds;
5. The condensation of the obtained products with amino acid or with each other.

In Maillard reaction, the basic amino group is the reactive component and therefore, the browning is dependent on the initial pH, or the presence of a buffer system. Low pH results in the protonation of the basic amino group, and therefore it inhibits the reaction. The effect of pH is also heavily dependent on the moisture content of the product. When the moisture is high, the browning is caused by caramelization, whereas at low water content and pH of about 6, the Maillard reaction prevails. The flavors produced by the Maillard reaction in some cases are reminiscent of caramelization.

The nonenzymic browning can be prevented by closely monitoring the factors leading to its occurrence, including temperature, pH, and moisture content. The use of inhibitors such as sulfite is an effective way of controlling nonenzymic browning. It is believed that sulfite reacts with the degradation products of the amino sugars to prevent the condensation of these products into melanoidins. However, sulfite can react with thiamine, which prohibits its use in foods containing this vitamin (Figs. 28.1 and 28.2).

FRUIT JUICE PROCESSING

The quality of the juice depends on the quality of the raw material, regardless of the process. Often, the quality of the fruit is dependent on the stage of maturity or the stage of ripening. The major physicochemical parameters used in assessing fruit ripening are sugar content, acidity, starch content, and firmness (Somogyi 1996a, 1996b).

The main steps involved in the processing of most type of juice include the extraction of the juice, clarification, juice deaeration, pasteurization, concentration, essence add-back, canning or bottling, and freezing (less frequent). Juice extractors for oranges and grapefruits, whose peel contain bitter oils, are designed to cause the peel oil to run down the outside of the fruit and not enter the juice stream. Since apples do not contain bitter oil, the whole apples are pressed. Juice extraction should be done as quickly as possible, in order to minimize oxidation of phenolic compounds in fruit juice by naturally present enzymes.

Apple Juice Processing

Apple juice is processed and sold in many forms including American apple cider, European apple cider, and shelf-stable apple juice. American apple cider is the product of sound, ripe fruit that has been pressed and bottled or packaged with no form of preservatives added and stored under refrigeration. This is a sweet type of cider, which has not been fermented. Because of an increased number of food-borne outbreaks of *E. coli* 0157:H7 and *Cryptosporidium parvum* in apple cider, many jurisdictions are working toward implementation of a kill step in the processing of apple cider. Several pathogen outbreaks make unpasteurized apple cider not suitable for general consumption, and especially for children, elderly, and immunocompromised people.

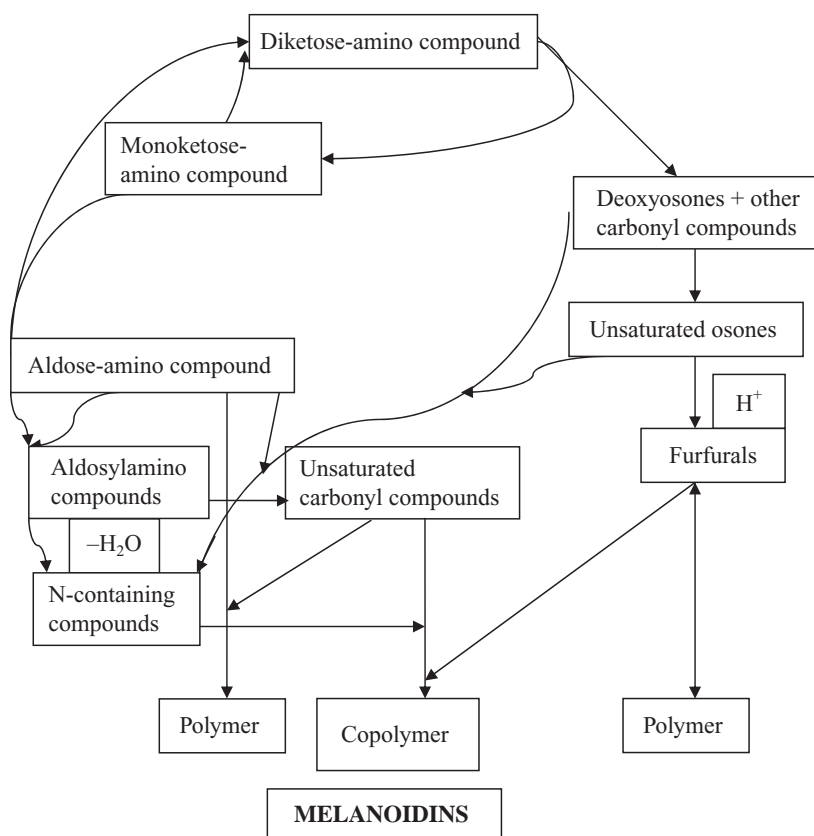
European type of apple cider is a naturally fermented apple juice, usually fermented to a specific gravity of one or less (Anonymous 1980). Shelf-stable apple juice includes clarified


Figure 28.1. Mechanism of browning reaction.

and crushed apple juice and concentrates. The most popular type of apple juice is the one that has been clarified and filtered before pasteurization and bottling. Natural juice is a juice that comes from the press. Up to 2% of ascorbic acid can be added before pasteurization and bottling in order to preserve the color. Crushed apple juice is produced by passing coarsely ground apples through a pulper and desecrator before pasteurization.

Juice concentrates can be two types: frozen, when the Brix is about 42°, or regular (commercial) concentrate with a Brix of 70° or more. Regardless of the type of apple product that is to be produced, the quality of the apple juice is directly related to the quality of the raw material used in its production. Only sound ripe fruits should be used in the processing of apple juice. "Windfalls" or apples that are fallen and picked from the ground, should not be used for the juice due to the risk of contamination by pathogens such as *E. coli* O157:H7, *C. parvum*, *Penicillium expansium* (producing the mycotoxin patulin) and also the risk of pronounced musty or earthy off-flavor of the juice. Overmature apples are very difficult to process, whereas immature apples give a starchy and astringent juice with poor flavor.

The processing of apple juice starts with washing and sorting of the fruit in order to remove soil and other foreign material as well as decayed fruits. Any damaged or decayed fruit should be removed or trimmed in order to keep down the level of patulin in the finished juice. Patulin is an indicator, which tells if the juice was produced from windfalls or spoiled apples. The acceptable level of patulin in most countries is less than 50 ppb. Patulin is carcinogenic and teratogenic. Various methods are currently used to reduce the levels of patulin in apple juice, namely, charcoal treatment, chemical preservation (sulfur dioxide), gamma irradiation, fermentation, and trimming of fungus-infected apples. A recent study shows that pressing followed by centrifugation resulted in an average toxin reduction of 89%. Total toxin reduction using filtration, enzyme treatment, and fining were 70, 73, and 77%, respectively, in the finished juice. (Bissessur et al. 2001). Patulin reduction was due to the binding of the toxin to solid substrates such as the filter cake, pellet, and sediment.

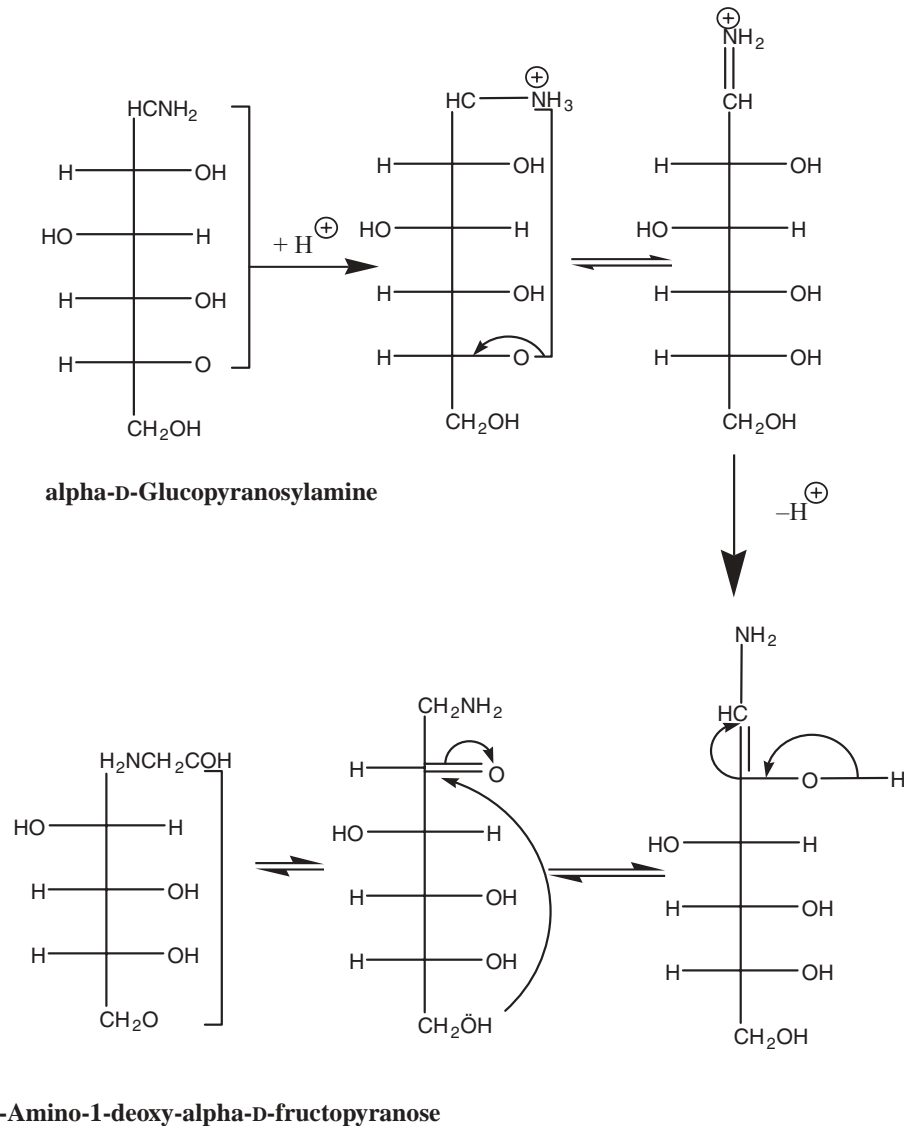
Prior to pressing, apples are ground using disintegrators, hammers, or grating mills. The effectiveness of the pressing operation depends on the maturity level of the fruits, as more mature fruits are often difficult to press. A wide range of presses is used in juice extraction including hydraulic, pneumatic, and screw/basket type. The vertical hydraulic is a batch-type press and requires no press aid. The main disadvantage is that the press is labor intensive and produces juice with low solids content. Hydraulic presses are the oldest type of press and are still used worldwide. The newer versions are automated and require


Figure 28.2. Amadori rearrangement in amino sugars.

press aid such as up to 1–2% paper pulp or rice hulls or both in order to reduce spillage and increase juice channel in the mash. The apple mash has many natural enzymes. Pectinolytic enzyme products contain the primary types of pectinases, pectinmethylesterase (PME), polygalacturonase (PG), pectin lyase, and pectin transeliminase (PTE). PME deesterifies methylated carboxylic acid moieties of pectin, liberating methanol from the side chain, after which PG can hydrolyze the long pectin chains (Fig. 28.3). Enzymatic mash treatment has been developed to improve the pressabiliy of the mash and, therefore the throughput and yield. An amount of 80–120 mL of enzyme per ton is added to the apple mash in order to break down the cell structure. High-molecular weight constituents of cell walls, like protopectin, are insoluble and inhibit the extraction of the juice

from the fruit and keep solid particles suspended in the juice. Pectinase used in the apple juice processing is extracted from the fungus *Aspergillus niger*. Pectinase developed for apple mash pretreatment acts mainly on the cell wall, breaking the structure and freeing the juice. Also, the viscosity of the juice is lowered, and it can emerge more easily from the mash. The high content of pectin esterase (PE) causes the formation of deesterified pectin fragments, which has a low water-binding capacity and reduces the slipperiness. These pectins consist of chains of galacturonic acid joined by alpha-glycoside linkage. In addition, polymers of xylose, galactose, and arabinose (hemicelluloses) form a link with the cellulose. The entire system forms a gel that retains the juice in the mash. The extraction is easier, even if the pectins are partially broken by pectinesterase. The pomace acts like a

pressing aid, when used with mash predraining. The application of enzyme treatment can increase the press throughput by 30–40% and the juice yield by over 20%. Mash pretreatment also increases the flux rate of ultrafiltered apple juice by up to 50%. An important by-product of apple juice industry is pectin. Therefore, overtreatment of mash with pectinolytic enzymes could render the pomace unsuitable for the production of pectin. Inactivation of the enzyme after reaching the appropriate level of pectin degradation is an important step in the production of apple juice. Residual pectic enzymes in apple juice concentrate could cause setup problems, when used for making apple jelly. There is a recent development in apple juice extraction with the process of liquefaction. Liquefaction is a process of completely breaking down the mash by using an enzyme preparation, tem-

perature, and time combination. The liquefied juice is extracted from the residual solid by the use of decanter centrifuges and rotary vacuum filters. It is a common practice, with the addition of cellulose enzyme to the mash to further degrade the cellulose to soluble solids, increasing the juice Brix nearly by 5°. The commercially available enzyme preparations contain more than 120 substrate specific enzyme components. Another popular extraction method is the countercurrent extraction method, developed in South Africa and refined in Europe in the 1970s. The principle of the system is as follows: the mash is heated, predrained, and counterwashed with water and recycled hot juice. A 90–95% recovery is possible when the throughput is about 3 tons per hour. The main disadvantage of the system is the lower soluble solids content of the obtained juice (6–8 vs. 11–12 from

other methods). Juice yield from different types of extraction varies from 75% to 95%, and depends on many factors including the cultivar and maturity of the fruit, the type of extraction, the equipment and press aids, the time, temperature, and the addition and concentration of the enzyme to the apple mash (Fig. 28.4).

Enzyme Applications

Enzyme applications in the apple juice processing follow the extraction, especially when producing a clarified type of juice. The main objective is to remove the suspended particles from the juice (Smock and Neubert 1950). The soluble pectin in the juice has colloidal properties and inhibits the separation of the undissolved cloud particles from the clear juice. Pectinase hydrolyzes the pectin molecule so it can no longer hold juice. The treatment dosage of pectinase depends on the enzyme strength and varies from one manufacturer to another. A typical '3X' enzyme dosage is about 100 mL per 4000 liters of raw juice. Depectinization is important for the viscosity reduction and the formation of galacturonic acid groups that helps flocculate the

suspended matter. This material, if not removed, binds to the filters, reduces the production, and can result in a haze formation in the final product. There are two methods of enzyme treatment commonly used in the juice industry including (1) hot treatment where the enzymes are added to $54°C$ juice, mixed, and held for 1–2 hours; and (2) cold treatment where the enzymes are added to the juice at reduced temperature ($20°C$) and held for 6–8 hours. The complete breakdown of the pectin is monitored by means of an acidified alcohol test. Five milliliters of juice are added to 15 mL of HCl-acidified, ethyl alcohol. Pectin is present if a gel develops in 3–5 minutes after mixing the juice with the ethanol solution. The absence of gel formation means the juice depectination is complete. In the cloud of the postprocessed juice, other polymers such as starch, and arabinans can be present and therefore, the clear juice is treated with alpha-amylase and hemicellulase enzymes, in order to partially or completely degrade them. Gelatin can be used to remove fragmented pectin chains and tannins from the juice. Best results are obtained when hydrating 1% gelatin in warm $60°C$ water. Gelatin can be added in combination with the enzyme treatment, bentonite, or by adding midway through the enzyme treatment period. The positively charged gelatin facilitates the removal of the negatively charged suspended colloidal material from the juice. Bentonite can be added in the range of 1.25–2.5 kg of re-hydrated bentonite per 4000 L of juice. Bentonite is also added to increase the efficiency of settling, protein removal, and prevention of cloudiness caused by metal ions. For cloudy and natural apple juice, enzymes are usually not used. The enzyme-treated, refined, and settled apple juice is then pumped from the settled material (lees) and further clarified by filtration.

The filtration of apple juice is done with or without a filter aid. The major types of filters are pressure leaf, rotary vacuum, frame, belt, and Millipore filters. To obtain the desired product color and clarity, most juice manufacturers use a filter medium or filter aid in the filtration process. The filter media include diatomaceous earth, paper pulp pads, cloth pads or socks, and ceramic membranes to name a few. The filter aid helps to prevent the blinding of the filters and increase throughput. As the fruit matures, more filter aid will be required. Several types of filter aids are available, in which the most commonly used is diatomaceous earth or cellulose-type materials. Additional juice can be recovered from the tank bottoms or "lees" by centrifugation or filtration. This recovered juice can be added to the raw juice before filtration.

Diatomaceous earth, or kieselguhr, is a form of hydrated silica. It has also been called fossil silica or infusorial earth. Diatomaceous earth is made up of the skeletal remains of prehistoric diatoms that were single-cell plant life and is related to the algae that grow in the lakes and oceans. Diatomaceous earth filtration is a three-step operation: (1) first, a firm thin protective precoat layer of filter aid, usually of cellulose, is built up on the filter septum (which is usually a fine wire screen, synthetic cloth, or felt); (2) the use of the correct amount of a diatomite body feed or admix (about 4.54 kg per 3000 cm^2 of filter screen); and (3) the separation of the spent filter cake from the septum prior to the next filter cycle. Prior to the filtration, centrifugation may be used to remove high-molecular weight suspended solids.
Figure 28.5. Membrane filtration. RO, reverse osmosis; UF, ultrafiltration; MF, microfiltration; F, filtration.

In some juice plants, high-speed centrifugation is used prior to the filtration. This centrifugation step reduces the solids by about 50%, thus minimizing the amount of filter aid required. The filtration process is critical, not only from the point of view of production, but also for the quality of the end product. Both pressure and vacuum filters have been used with success in juice production (Nelson and Tresler 1980). A recent development in the juice industry is the membrane ultrafiltration. Ultrafiltration, based on membrane separation, has been used with good results to separate, clarify, and concentrate various food products. Ultrafiltration of apple juice will not only clarify the products, but depending on the size of the membrane, will also remove the yeast and mold microorganisms common in apple juice (Fig. 28.5).

Apple Juice Preservation

Preservation of apple juice can be achieved by refrigeration, pasteurization, concentration, chemical treatment, membrane filtration, or irradiation. The most common method is pasteurization based on temperature and time of exposure. The juice is heated to over 83°C, held for 3 minutes, filled hot into the container (cans or bottles), and hermetically sealed. The apple juice is held for 1 minute at 83°C and then cooled to less than 37°C. When containers are closed hot and then cooled, vacuum develops, reducing the available oxygen that also aids in the prevention of microbial growth. After the heat treatment, the juice may also

be stored in bulk containers. Aseptic packaging is another common process where, after pasteurization, the juice is cooled and packed in a closed, commercially sterile system under aseptic conditions. This process provides shelf-stable juice in laminated, soft-sided consumer cartons, bag-in-box cartons, or aseptic bags in 200–250 liter drums.

Apple juice concentration is another common method of preservation. The single-strength apple juice is concentrated by evaporation, preferably to 70° or 71° Brix. By an alternate method, the single-strength juice is preconcentrated by reverse osmosis to about 40° Brix, then further concentrated by evaporation methods. The reduced water content and natural acidity make the final concentrated apple juice shelf stable at room temperature. There are several evaporators used in apple juice production including rising film evaporators, falling film evaporators, and multiple effect tubular and plate evaporators. Due to the heat sensitivity of the apple juice, the multiple-effect evaporator with aroma recovery is the most commonly used. The general method in a multiple-effect evaporator is to heat the juice to about 90°C and capture the volatile (aroma) components by cooling and condensation. This is followed by reheating the 20–25° Brix juice concentrate in the first stage to about 100°C and then concentrate it to about 40–45° Brix. Another stage of heating and evaporation at about 50°C to 60° Brix, and final heating and concentration in the fourth stage to 71° Brix provides fully concentrated juice. The warm concentrate is then chilled to 4–5°C prior to adjusting the Brix to 70° before barreling or bulk storage.

Chemicals such as benzoic acid, sorbic acid, and sulfite are sometimes used to reduce spoilage of unpasteurized apple juice, either in bulk or as an aid in helping to preserve refrigerated products. Application of irradiation and ultrasonic sound are new emerging methods of preservation with high potential even though not fully accepted by consumers at this time.

Apple essence is recovered during the concentration of apple juice. The identification of volatile apple constituents, commonly known as essence or aroma, has been the subject of considerable research. In 1967, researchers at the USDA identified 56 separate compounds from apple essence. These compounds were further refined by organoleptic identification, using a trained panel of sensory specialists. These laboratory evaluations revealed 18 threshold compounds identified as "Delicious" apple compounds consisting of alcohols, aldehydes, and esters. Three of the eighteen compounds had "apple-like aromas" according to the taste panel. These were 1-hexanal, trans-2-hexenal, and ethyl, 2-methyl butyrate (Flath et al. 1967, Somogyi et al. 1996b).

Processed Apple Products

The popularity of blended traditional/tropical juice products has pushed the consumption of traditional fruit juices such as apple, orange, and grape juices to 25 liters in 2002, an increase of more than 24% from 1992 (Statistics Canada 2003). Apples are normally processed into a variety of products, although apple juice is the most popular processed apple product. With a production of 465,418 metric tons of apple in 2001, Canada exported

18,538 metric tons of concentrated apple juice. For the same year, United States exported 25,170 metric tons of concentrated apple juice (FAO 2003). Apples for processing should be of high quality, proper maturity, of medium size, and uniform in shape. Apples are processed into frozen, canned, dehydrated apple slices and dices, and different kinds of applesauce. Apples that are unsuitable for peeling are diverted to juice processing.

Apple Sauce

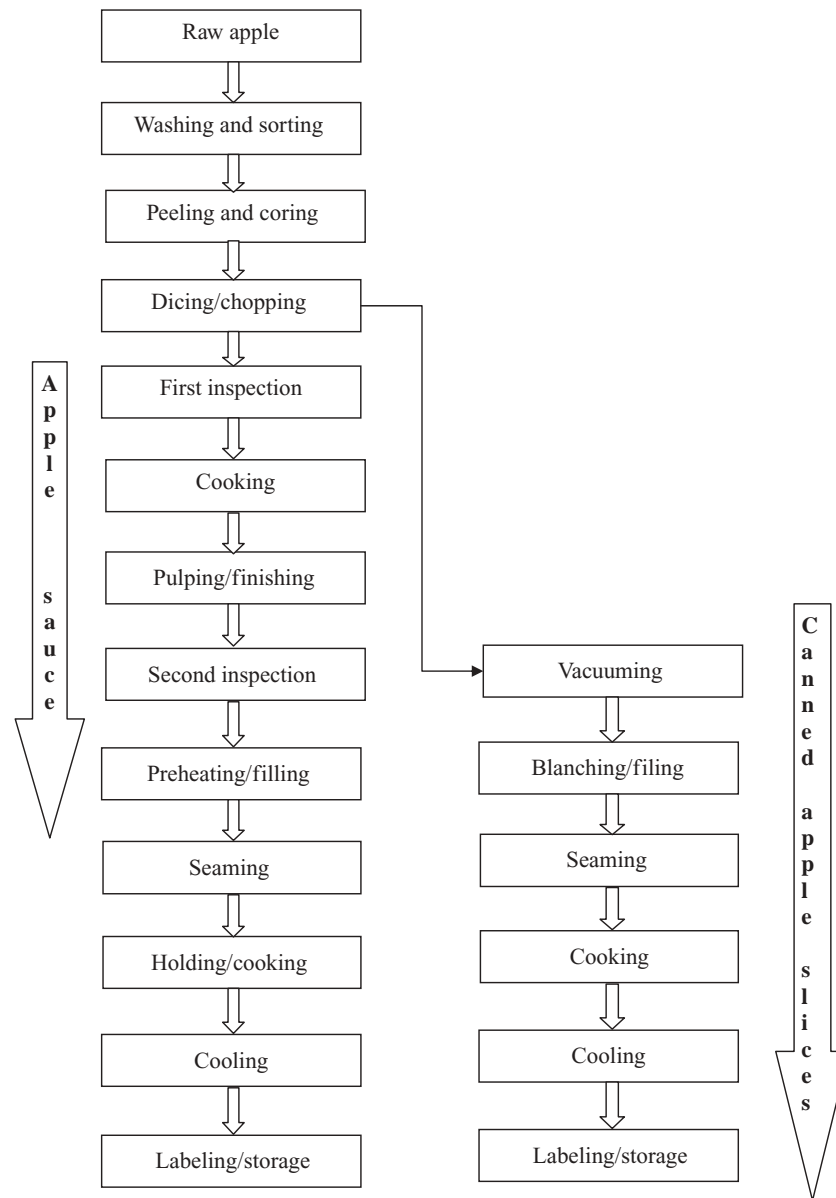
Diced or chopped apples with added sugar, preferably a sugar concentrate, are cooked at 93–98°C for 4–5 minutes in order to soften the fruit and inactivate polyphenol oxidase. Sauce with a good texture, color, and consistency is produced with high quality raw apples and a good combination of time and temperature treatment. Cooked applesauce is passed through a pulper of 1.65–3.2 mm finishing screen to remove unwanted debris and improve the texture. Applesauce is then heated to 90°C and immediately filled in glass jars or metal cans. The filled applesauce are seamed or capped at 88°C and cooled to 35–40°C after 1–2 minutes (Fig. 28.6). There are various types of applesauce that include natural, no sugar added, "chunky", cinnamon applesauce, and mixture of applesauce and other fruits such as apricot, peach, or cherry.


Figure 28.6. A flow chart depicting steps in apple processing.

Sliced Apples

Sliced apples have multiple uses and are preserved by many different methods such as canned, refrigerated, frozen, or dehydrated states. About 85% of sliced apples are processed, whereas only 15% are refrigerated, frozen or dehydrated and frozen. Apple slice texture is very important, as well as the consistency of the slice size, therefore, apples with firm flesh and high-quality, falling within a specified size range are desirable. Apples are sliced into 12–16 slices and blanched after inspection for eventual defects. The blanched apple slices are hot filled into cans and closed under steam vacuum after addition of hot water or sugar syrup. The canned apples are heated at 82.2°C and immediately cooled to 37–40°C.

When bulk frozen, apple slices are vacuum treated and blanched and filled into 13–15 kg tins or poly-lined boxes. The tins or boxes are then sealed, frozen, and stored at −17°C.

Individual quick frozen apple slices (IQF) are usually treated with sodium bisulfite after inspection. Nitrogen (N_2) and carbon dioxide (CO_2) are the most popular freezing media. From the vacuum tank, the apple slices pass through an IQF unit where the slices are individually frozen. From the freezing unit, the slices are filled into tins or poly-lined boxes and stored frozen at −17°C or below.

Dehydrofrozen apple slices are dehydrated to less than 50% of their original weight and then frozen. The dehydrofrozen slices are packed in cardboard containers or large metal cans with polyethylene liners and rapidly frozen before storing. Frozen slices are thawed and then soaked in a combined solution of sugar, $CaCl_2$, and ascorbic acid, or bisulfite. For fresh and refrigerated apple slices, the use of 0.1–0.2% calcium chloride, and ascorbate protects apple slices from browning and microbial spoilage. Blanched slices resist browning for approximately 2 days, but lose flavor, sugar, and acid. This type of product has a very short shelf life. Recently, the use of natural protein polymer coatings (NatureSeal) has shown promise in enhancing the shelf life and quality of fresh-cut apple products.

Dried Apple Products

Most processing cultivars are used for drying, but the best quality dried apple slices are obtained from "Red Delicious" and "Golden Delicious" apples. A desirable quality attribute of apples used for drying is a high sugar/water ratio. Color preservation and reduction in undesirable enzyme activities are achieved by the use of bisulfite. There are two types of dried apple products including evaporated and dehydrated apples. Evaporated apples are cut into rings, pie pieces, or dices and then dried to less than 24% moisture by weight. The dehydrated apples, on the other hand, are cut into dices, pie pieces, granules, and flakes prior to drying to 3–0.5% moisture content. Up to 300 ppm of bisulfite is used to prevent color deterioration. The maximum allowed SO_2 in dried apples in Europe is 500 ppm, whereas in United States, the limit is 1000 ppm.

QUALITY CONTROL

Apples contain several organic acids and as such, only a limited number of microorganisms can grow in them. The most common microbes are molds, yeasts, aciduric bacteria, and certain pathogens such as *E. coli* O157:H7, capable of growing at low pH (Swanson 1989). Several approaches to quality management are available today including total quality management (TQM), statistical quality control (SQC), and hazard analysis critical control points (HACCP).

BIOCHEMICAL COMPOSITION AND NUTRITIONAL VALUE OF PROCESSED APPLES

The nutritive value of most processed apple products is similar to the fresh raw product. Apple products are sources of potassium, phosphorus, calcium, vitamin A, and ascorbic acid. Glucose, sucrose, and fructose are the most abundant sugars. Dried or dehydrated apples have a higher energy value per gram tissue due to the concentration of sugars (Tables 28.4 and 28.5).

The nutritional value of apples, and fruits in general, is enhanced by the presence of flavonoids. More than 4000 flavonoids have been identified to date. There are many classes of flavonoids of which flavanones, flavones, flavonols, isoflavonoids, anthocyanins, and flavans are of interest. Flavanones occur predominantly in citrus fruits, anthocyanins, catechins, and flavonols are widely distributed in fruits, and isoflavonoids are present in

Figure 28.7. Chemical structures of fruit flavonoids. The propanoid structure consists of two fused rings. "A" is aromatic ring and "C" is a heterocyclic ring attached by carbon–carbon bond to "B" ring. The flavonoids differ in their structure at the "B" and "C" rings.

legumes. Structurally, flavonoids are characterized by a C_6-C_3-C_6 carbon skeleton (Fig. 28.7). They occur as aglycones (without sugar moieties) and as glycosides (with sugar moieties). Processing may decrease the content of flavonoids by up to 50%, due to leaching into water or removal of portions of the fruit such as the skin, that are rich in flavonoids and anthocyanins. It is estimated that the dietary intake of flavonoids may vary from 23 mg/d to 1000 mg/d in various populations (Peterson and Dwyer 1998). Flavonoids are increasingly recognized as playing potentially important roles in health including but not limited to their roles as antioxidants. Epidemiological studies suggest that flavonoids may reduce the risk of developing cardiovascular diseases and stroke.

Flavanones

The major source of flavanones is citrus fruits and juices. Flavanones contribute to the flavor of citrus, for example, naringin found in grapefruit provides the bitter taste, whereas hesperidin, found in oranges is tasteless.

Flavonols

The best-known flavonols are quercetin and kaempferol. Quercetin is ubiquitous in fruits and vegetables. Kaempferol is most common among fruits and leafy vegetables. In fruits, flavonols and their glycosides are found predominantly in the skin. Myricetin is found most often in berries.

Table 28.6. Nutrients in Fruit and Processed Products (454 g)

Anthocyanins

Anthocyanins often occur as a complex mixture. Grape extracts can have glucosides, acetyl glucosides, and coumaryl glucosides of delphinidin, cyanidin, petunidin, peonidin, and malvidin. The color of anthocyanins is pH dependent. An anthocyanin is usually red at a pH of 3.5, becoming colorless and then shifting to blue as the pH increases. Fruit anthocyanin content increases with maturity. In stone fruits (peaches and plums) and pome fruits (apple and pears), anthocyanins are restricted to the skin, whereas in soft fruits (berries), they are present both in skin and flesh. Anthocyanins are used as coloring agents for beverages and other food products.

Flavans

Flavans are what was once called catechins, leucoanthocyanins, proanthocyanins, and tannins. They occur as monoflavans, biflavans, and triflavans. Monoflavans are found in ripe fruits and fresh leaves. Biflavans and triflavans are found in fruits such as apples, blackberries, blackcurrants, cranberries, grapes, peaches, and strawberries (Table 28.6).

Biochemistry of Vegetable Processing

Moustapha Oke, Jissy K. Jacob, and Gopinadhan Paliyath

Abstract: Vegetables are very important components of diet. Vegetables are highly perishable, and transportation, storage, and distribution require low-temperature conditions. Vegetables are processed into juice, sauce, and canned under aseptic conditions. This enables long-term storage of processed products. Tomato is the major produce that is processed into juice and sauce. Preservation of nutritional components is compromised during processing. Stability of juice is influenced by the particle size distribution.

INTRODUCTION

Vegetables and fruits have many similarities with respect to their composition, harvesting, storage properties, and processing. In the true botanical sense, many vegetables are considered as fruits. Thus, tomatoes, cucumbers, eggplant, peppers, and so on could be considered as fruits, since they develop from ovaries or flower parts and are functionally designed to help the development and maturation of seeds. However, the important distinction between fruits and vegetables is based on their use. In general, most vegetables are immature or partially mature and are consumed with the main course of a meal, whereas fruits are generally eaten alone or as a dessert. The United States is one of the world's leading producers and consumers of

World vegetable supply

World vegetable supply

vegetables and fruits. In 2002, the farm gate value of vegetables and melons (including mushrooms) sold in the United States reached $17.7 billion. Annual per capita use of fresh vegetables and melons rose 7% between 1990–1992 and 2000–2002, reaching 442 pounds, as fresh consumption increased and consumption of processed products decreased. According to Food and Agriculture Organization (FAO) data, the world production of vegetables has increased from 147 million metric tons (Mt) in 1992 to 350 million Mt in 2005 (Fig. 29.1). Potato, tomato, sweet potato, onions and so on are the major vegetables that are produced across the world (Fig. 29.1). Vegetables remain a popular choice for consumers worldwide. In general, the supply of vegetables per capita has increased in developing countries, but lags behind in certain parts of the world (Table 29.1). In 2002, each individual ate an average of 110

Types of Vegetables	Examples
Earth vegetables	
Roots	Sweet potatoes, carrots
Modified stems	
Corms	Taro
Tubers	Potatoes
Modified buds	
Bulbs	Onions, garlic
Herbage vegetables	
Leaves	Cabbage, spinach, lettuce
Petioles (leaf stalk)	Celery, rhubarb
Flower buds	Cauliflower, artichokes
Sprouts, shoots (young stems)	Asparagus, bamboo shoots
Fruit vegetables	
Legumes	Peas, green beans
Cereal	Sweet corn
Vine fruits	Squash, cucumber
Berry fruits	Tomato, eggplant
Tree fruits	Avocado, breadfruit

kilograms of vegetables (including potatoes), up from 106 kg a decade earlier. Potatoes represented 35% of all vegetables consumed. In 2008, greater than 50% of women and nearly 40% of men reported to have more than 5 servings of fruits and vegetables per day. (http://www.statcan.gc.ca/pub/82-229-x/2009001/deter/fvc-eng.htm.) The world production of certain vegetables is shown in Tables 29.2 and 29.3. From 2002 to 2005, the increase in vegetable production observed was primarily due to an increase in production of potatoes (Fig. 29.1).

In the United States, consumption of fresh vegetables (excluding potatoes) has increased from 60 kg in 1986 to 72 kg in 2003. In 2003, the most consumed fresh vegetable was head lettuce at 12 kg, followed by onions at 9 kg and fresh tomatoes at 8 kg. In the same year, the consumption of processed tomatoes per capita was 35 kg and processed sweet corn 9.5 kg. In Canada, the consumption of fresh vegetables (excluding potatoes) has been increasing steadily reaching 70.2 kg/capita in 1997 from 41 kg/capita in 1971. Also in 1997, the consumption of fresh vegetables has declined 2.4% from the amount of fresh vegetables consumed in 1996 (71.9 kg/capita). Lettuce (16%) is the most consumed fresh vegetable followed by onions (12.1%), carrots (12.0%), tomatoes (11.6%), and cabbage (8.1%). Brussels sprouts, parsnips, asparagus, beets, and peas each represent less than 1.0% of Canadian fresh vegetable diet. On a per capita basis, Canada has one of the highest consumption rates of fresh vegetables in the world. Frozen vegetable consumption has de-

clined 3.4% to 5.6 kg/capita while canned vegetables and vegetable juices have increased 2.4% to 12.9 kg/capita for the same period. Vegetable purchases by consumers represent 6.6% of total food expenditures, virtually unchanged in the past 10 years.

CLASSIFICATION OF VEGETABLES

Vegetables can be classified according to the part of the plant from which they are derived, such as leaves, roots, stems, and buds as shown in Table 29.4. They also can be classified into "wet" or "dry" crops. Wet crops such as celery or lettuce have water as their major component, whereas dry crops such as soybeans have carbohydrates, protein, and fat as their major constituents, and relatively low amount of water. Soybeans, for example, are composed of 36% protein, 35% carbohydrate, 19% fat, and 10% water. Wet crops tend to perish more rapidly compared to dry crops.

CHEMICAL COMPOSITION OF VEGETABLES

Fresh vegetables contain more than 70% water, and very frequently greater than 85%. Beans and other dry crops are exceptions. The protein content is often less than 3.5% and the fat content less than 0.5%. Vegetables are also important sources of digestible and indigestible carbohydrate, as well as of minerals and vitamins. They contain the precursor of vitamin A, beta-carotene, and other carotenoids. Carrots are one of the richest sources of beta-carotene (provitamin A).

Table 29.3. Production of Tomato in North America

Tomato Production (Mt)	Year 2002
World	108,499,056
Canada	690,000
United States of America	12,266,810
Mexico	2,083,558

VITAMINS

Vegetables are major contributors to our daily vitamin requirements. The nutrient contribution from a specific vegetable is dependent on the amount of vitamins present in the vegetable, as well as the amount consumed. The approximate percentage that vegetables contribute to daily vitamin intake is: vitamin A-50%, thiamine-60%, riboflavin-30%, niacin-50%, and vitamin C-100%. Vitamins are sensitive to different processing conditions including; exposure to heat, oxygen, light, free water, and traces of certain minerals. Trimming, washing, blanching, and canning can cause loss in vitamin content of fruits and vegetables.

MINERALS

The amount and types of minerals depend on the specific vegetable. Not all minerals in plant materials are readily available and are mostly in the form of complexes. An example is calcium found in vegetables as calcium oxalate. Green leafy vegetables are rich in magnesium and iron.

DIETARY FIBER

The major polysaccharides found in vegetables include starch, and dietary fiber such as cellulose, hemicellulose, pectic substances, and lignin. Cell walls in young vegetables are composed of cellulose. As the produce ages, cell walls become higher in hemicellulose and lignin. These materials are tough and fibrous and their consistency is not affected by processing. Some vegetables such as potato also contain varying amounts of starch resistant to hydrolysis (resistant starch). Resistant starch is not digested as efficiently as regular starch, and reaches the colon where they undergo microbial fermentation. The short chain fatty acids liberated during the digestion of resistant starch is considered to be beneficial to the health. Roots of vegetables such as endive are rich in fructooligosaccharides such as inulin, which are considered to possess health regulatory function.

PROTEINS

Most vegetables contain less than 3.5% protein. Soybeans are an exception. In general, plant proteins are major sources of dietary protein in places where animal protein is in short supply. Plant proteins, however, are often deficient or limiting in one or more essential amino acids. Wheat protein is limiting in lysine, while soybean protein is limiting in methionine. Leafy green vegetables are also rich in proteins, especially photosynthetic proteins such as ribulose-bis-phosphate carboxylase oxygenase (RubisCO) and other chloroplast proteins. Multiple sources of plant proteins are recommended in the diet because of the absence of key amino acids.

LIPIDS

The lipid content of vegetables is less than 0.5% and primarily found in the cuticles, as constituents of the cell membrane, and in some cases, as a part of the internal cell structure (oleosomes). Even though lipids are a minor component of vegetables, they play an important role in the characteristic aroma and flavor of the vegetable. The characteristic aroma of cut tomato and cucumber results from components released from the lipoxygenase pathway, through the action of lipoxygenase upon linoleic and linolenic acids and the hydroperoxide lyase action on the peroxidized fatty acids to produce volatile compounds. This action is accentuated, when the tissue is damaged. The results of the action of lipoxygenase are sometimes deleterious to the quality—for example, the action of lipoxygenase on soybean oil leads to rancid flavors and aromas.

VOLATILES

The specific aroma of vegetables is due to the amount and diversity of volatiles they contain. Volatiles are present in extremely small quantities (<100 ug/g fresh wt). Characteristic flavors and aromas are a combination of various compounds, mainly short chain aldehydes, ketones, and organic acids. Their relative importance depends upon threshold concentration (sometimes < 1 ppb), and interaction with other compounds. Of more than 400 volatiles identified in tomato, the following have been reported to play important roles in fresh tomato flavor: hexanal, trans-2-hexenal, cis-3-hexenal, cis-3-hexenol, trans-2-trans-4 decadienal, 2-isobutylthiazole, 6-methyl-5-hepten-2-one, 1-penten-3-one, and β-ionone (Petro-Turza 1986–1987).

WATER

In general, water is the most abundant single component of most vegetables (up to 90% of total weight). The maximum water content of vegetables varies between individuals due to structural differences. Agricultural conditions also influence the water content of plants. As a major component of vegetables, water impacts both on the quality and the rate of deterioration. Harvest should be done during the cool part of the day in order to keep the turgidity to its optimum. Loss of turgor under post harvest storage is a major quality-reducing factor in vegetables (wilting of leaves such as spinach).

ORGANIC ACIDS

Organic acids are important contributors to the taste and flavor of many vegetables (tomato). Total titratable acidity, the quantity and specificity of organic acids present in vegetables influence the buffering system and the pH. Acid content decreases during maturation, because of its use for respiration and transformation into sugars through gluconeogenesis. Certain fruits are used as vegetables when immature. For example, immature mango fruits, which are rich in organic acids, are used as vegetables.

PIGMENTS

Pigments are mainly responsible for the skin and flesh colors in vegetables. The vegetables undergo changes during maturation and ripening of vegetables, including loss of chlorophyll

(green color), synthesis and/or revelation of carotenoids (yellow and orange) and development of anthocyanins as in eggplant (red, blue and purple). Vegetables such as carrots are especially rich in beta-carotene, and red beets owe their red color to betacyanins. Tomatoes are a rich source of the red carotenoid lycopene. Anthocyanins belong to the group of flavonoids, occur as glycosides, and are water-soluble. They are unstable and easily hydrolyzed by enzymes to free anthocyanins. The latter are oxidized to brown products by phenoloxidases. The colors of anthocyanins are pH dependent. In basic medium, they are mostly violet or blue, whereas in acidic medium they tend to be red. Several exotic new vegetables with different colors have been introduced recently, that include purple carrots and tomatoes containing anthocyanins, yellow, and green cauliflower (broccoflower) and so on with added characters than their parental crops.

PHENOLIC COMPONENTS

Phenolic compounds found in vegetables vary in structure from simple monomers to complex tannins. Under most circumstances they are colorless, but after reaction with metal ions, they assume red, brown, green, gray, or black coloration. The various shades of color depend on the particular tannins, the specific metal ion, pH, and the concentration of the phenolic complex. Phenolics, which are responsible for the astringency in vegetables, decrease with maturity, because of the conversion of astringent phenolics from soluble to insoluble form (egg plant, plantain).

CARBOHYDRATES

The carbohydrate content of vegetables is between 3% and 27% (Table 29.5). Carbohydrates vary from low molecular weight sugars to polysaccharides such as starch, cellulose, hemicellulose, pectin, and lignin. The main sugars found in vegetables are glucose, fructose, and sucrose. In general, vegetables contain higher amount of polysaccharides (starch). Root vegetables are rich in starch (e.g., taro and colocasia, various yams, tapioca, sweet potato, potato). Plantains are also rich in starch. Fruits of the Artocarpaceae family (jack fruit, bread fruit) are also rich in starch prior to their ripening, when they are used as vegetables.

TURGOR AND TEXTURE

The predominant structural feature of vegetables is the presence of parenchyma cells that are assembled into metabolically and functionally important regions for their function. In leaf tissues, the parenchymal cells are organized to obtain photosynthetic efficiency. In root tissues, the cells are loaded with starch granules. The texture of vegetables is largely related to the elasticity and permeability of the parenchyma cells. Cells with high content of water exhibit a crisp texture. The cell vacuoles contain most of the water of plant cells. The vacuolar solution contains dissolved sugars, acids, salts, amino acids, pigments and vitamins, and several other low-molecular-weight constituents. The osmotic pressure within the cell vacuole, and within the protoplast against the cell walls, causes them to stretch slightly in accordance with their elastic properties. These processes determine the specific appearance and crispness of vegetables. Damaged vegetables lose their turgor after processing and tend to become soft unless precautions are taken in packaging and storage.

VEGETABLE PROCESSING

HARVESTING AND PROCESSING OF VEGETABLES

The quality of the vegetables constantly varies depending on the growth conditions. Since the optimum quality is transient, harvesting and processing of several vegetables such as corn, peas, and tomatoes are strictly planned. Serious losses can

Table 29.5. Percentage Composition of Vegetables

Food	Component				
	Carbohydrate	Protein	Fat	Ash	Water
Cereals					
Maize (corn) whole grain	72.9	9.5	4.3	1.3	12
Earth vegetables					
Potatoes, white	18.9	2.0	0.1	1.0	78
Sweet potatoes	27.3	1.3	0.4	1.0	70
Other Vegetables					
Carrots	9.1	1.1	0.2	1.0	88.6
Radishes	4.2	1.1	0.1	0.9	93.7
Asparagus	4.1	2.1	0.2	0.7	92.9
Beans (snap−, green−)	7.6	2.4	0.2	0.7	89.1
Peas, fresh	17.0	6.7	0.4	0.9	75.0
Lettuce	2.8	1.3	0.2	0.9	94.8

Source: Food and Agriculture Organization (FAO).

occur when harvesting is done before or after the peak quality stage. The time of harvesting vegetables is very important to the quality of the raw produce and the manner of harvesting and handling is critical economically. A study on sweet corn showed that 26% of total sugars were lost in just 24 hours by storing the harvested corn at room temperature. Even when stored at low temperature, the sugar loss could reach 22% in 4 days. Peas and lima beans can lose up to 50% of their sugars in just 1 day. Losses are slower under refrigeration but the reduction in sweetness and freshness of the produce is an irreversible process. It is assumed that a part of the sugars is used for respiration and starch formation in commodities such as corn, whereas the sugars are converted to cellulose, hemicellulose, and lignin in the case of asparagus. Each type of vegetable has its optimum cold storage temperature, which may vary between $0°C$ and $10°C$. Water loss is another problem, which reduces the quality of the produce. Continued water loss due to transpiration and drying of cut surfaces results in wilting of leafy vegetables. Hermetic packaging (anaerobic packaging) does not prevent water loss, but instead creates conditions that prevent deterioration due to an increase in the level of carbon dioxide and a decrease in the oxygen level. In order to keep consistent produce quality, many processors monitor the growing practices so that harvest and processing are programmed according to the capacity of the processing plant.

PREPROCESSING OPERATIONS

Vegetables can be processed in different ways including canning, freezing, freeze-drying, pickling, and dehydration. The operations involved in the processing depend on the type of vegetable and the method to be used. After harvest, the processing steps involved in canning are washing, sorting and grading, peeling, cutting and sizing, blanching, filling and brining (brining is very important for filling weight and heat transfer), exhausting (help maintaining high vacuum; exhaust temperature in the center of the can should be about $71°C$), sealing, processing (heating cycle), cooling, labeling, and storage.

Harvesting

Decision to harvest should be based on experience and on objective testing method. It is recommended that the vegetables be harvested at the optimum maturity and processed promptly (Luh and Kean 1988, Woodroof 1988).

Sorting and Grading

This operation is done using roller grader, air blower, rod shaker, or any mechanical device, followed by sorting on conveyor belts. Electronic sorting is commonly used recently to remove vegetables affected by diseases and insects.

Washing

Vegetables are washed to remove not only field soil and surface microorganisms, but also fungicides, insecticides, and other pesticides. There are laws specifying the types and maximum levels of contaminants that are permitted. In order to remove dirt, insects, and small debris, vegetables are rinsed with water or with detergent in some cases. Mechanically harvested tomatoes, potatoes, red beets, and leafy vegetables are washed with fruit grade detergents. The choice of washing equipment depends on the size, shape, and fragility of the particular type of vegetable. Flotation cleaners can be used for peas and other small vegetables, whereas fragile vegetables such as asparagus may be washed by gentle spraying belt.

Peeling

Several methods are used to remove skins from vegetables including lye, steam, and direct flame. Lye peeling of mechanically harvested tomatoes and potatoes is a common practice. Vegetables with loosened skins are jet washed with water to remove skins and residual sodium hydroxide. Steam is used to peel vegetables with thick skin such as red beets and sweet potatoes, whereas for onions and pepper direct flame or hot gases in rotary tube flame peelers are used.

Cutting and Trimming

Cutting, stemming, pitting, or coring depends on the type of vegetable. Asparagus spears are cut to precise lengths. The most fibrous part is used for soup and other heated products where heat tenderizes them. Green beans are cut by machine into several different shapes along the length of the vegetable. Brussels sprouts are trimmed by hand by pressing the base against a rapidly rotating knife. Olives are pitted by aligning them in small cups, and mechanically pushing the plungers through the olives.

Blanching

The purpose of blanching is to inactivate the enzymes present in the vegetables. Since many vegetables do not receive a high-temperature heat treatment, heating to a minimal temperature before processing or storing inactivates the enzymes responsible for changes in texture, color, flavor and nutritional quality of the produce. Several enzymes are responsible for the loss of quality in vegetables. The deterioration of the cell membrane caused by the action of phospholipase D and lipoxygenases account for the flavor development in vegetables (Pinhero et al. 2003, Oke et al. 2003). Proteases and chlorophyllases contribute to the destruction of chloroplast and chlorophyll. Changes in texture occur due to the activity of pectic enzymes and cellulases. Color deterioration occurs due to the activity of polyphenol oxidase, chlorophyllase, and peroxidase (Robinson 1991). Changes in nutritional quality can occur by the activity of enzymes that destroy the vitamins. Ascorbic acid oxidase can cause a decline in the level of vitamin C.

The blanching process also reduces the microbial load of vegetables and renders packaging into containers easier. To evaluate the effectiveness of blanching, indicator enzymes such as catalase and peroxidase are traditionally used. The reason for using indicators is that blanching is not a process of indiscriminate

Table 29.6. Relative Content of Vitamins in Peas During Processing

Processing	Vitamins, Percentage of Original			
	C	B1	B2	Niacin
Fresh	100	100	100	100
Blanched	67	95	81	90
Blanched/frozen	55	94	78	76
Blanched, frozen, cooked	38	63	72	79

heating, meaning too little heating is ineffective, whereas heating too much on the other hand, negatively impacts the freshness of certain vegetables. The choice of an indicator depends on the vegetable being processed. For example, lipoxygenase may be an ideal indicator for peas and beans. The problem with using peroxidase as a universal indicator is that it sometimes overestimates heat requirements, which may vary from one product to another. Blanching prior to freezing has the advantages of stabilizing color, texture, flavor, and nutritional quality, as well as helping the destruction of microorganisms. Blanching, however, can cause deterioration of taste, color, texture, flavor, and nutritional quality, because of heating (Table 29.6.). There are three ways of blanching a produce including blanching using water, steam, or microwave. Blanchers need to be energy efficient, to give a uniform heat distribution and time, to have ability to keep quality of the produce while destroying enzymes and reducing microbial load. Blanching using water is done at 70–100°C for a specific time frame, giving a thermal energy transfer efficiency of about 60%, versus 5% for steam blanchers. Time-temperature combination is very important in order to inactivate enzymes and keeping the quality of vegetables. Effects of blanching on plant tissues include alteration of membranes, pectin demethylation, protein denaturation, and starch gelatinization. Microwave blanching gives similar result as water blanching, but the loss of vitamins is higher than in steam and water methods (Table 29.7.)

Canning Procedure

Depending on their pH, vegetables can be grouped into four categories (Banwart 1989), including high-acid vegetables with pH

Table 29.7. Effect of Blanching Methods on Vitamin C Content

	Vitamin C (mg/100g Fresh Weight)			
	Asparagus	Beans	Peas	Corn
Water	35.7	22.5	15.6	15.8
Steam	35.3	23.3	11.0	13.6
Microwave	18.9	13.1	9.3	12.9

< 3.7, acid vegetables with pH 3.7–4.6, medium-acid vegetables with pH 4.6–5.3, and low-acid vegetables with pH > 5.3.

The purpose of canning is to ensure food safety and high quality to the product, as the growth of several pathogens may compromise these parameters. *Clostridium botulinum* (*C. botulinum*), an anaerobic and neuroparalytic toxin-forming bacterium, is a primary safety concern in hermetically sealed, canned vegetables. Other important spoilage organisms include *Clostridium sporogenes* group including putrefactive anaerobe 3679, *Clostridium thermosaccharolyticum*, *Bacillus stearothermophilus* and related species (Stumbo et al. 1975). Although *C. botulinum* spores do not produce toxin, the vegetative cells formed after germination produce a deadly neurotoxin in canned low-acid vegetables. Botulism, the poisoning caused by the *C. botulinum* is mostly associated with canned products including vegetables. Canned vegetables are commercially sterile, meaning that all pathogens and spoilage organisms of concern have been destroyed. The product may still contain a few microbial spores that could be viable under better conditions. During the processing of low-acid vegetables, it is necessary to provide a margin of safety in the methods schedule. This is achieved according to a "12D" process. D-value for a given temperature is taken from a thermal death time (TDT) curve. D-value is the time in minutes required to kill 90% of a bacterial population. The assumption is that by increasing this time by 12, any population of *C. botulinum* present in the canned product will decrease by 12 log cycles. This process time allows for adequate reduction of bacterial load to achieve a commercially sterile product.

$$t = D(\log a - \log b) \qquad (1)$$

where

$t =$ heating time in minutes at a constant lethal temperature
$D =$ time in minutes to kill 90% of a bacterial population
$\log a =$ log of initial number of viable cells
$\log b =$ log of number of viable cells after time t

For *C. botulinum*, with $D = 0.21$ at 121°C, the 12D is equal to 2.52 minutes (12×0.21 min), which means, if a can contains one spore of C. botulinum with this D value, then it can be seen from the above equation that $2.52 = 0.21$ (log 1 − log b), or $\log b = -2.52/0.21 = -12$; therefore $b = 10^{-12}$. The probability of survival of a single *C. botulinum* spore in the can is one in 10^{12} (Hersom and Hulland 1980). In canning low and medium-acid vegetables, where the destruction of spores of *C. botulinum* is the major concern, a 12D process (2.52 minutes or 3 minutes at 121°C) is the minimum safe standard for the "botulinum cook" (Banwart 1989).

CANNED TOMATOES

Tomato, *Lycopersicon esculentum* Mill., belongs to the family of Solanaceae. Tomato is a major vegetable crop in North America. In North America alone, over 15 million Mt of processing tomatoes are produced. Canned tomatoes are prepared from red ripe tomatoes as whole, diced, sliced, or wedges. The fruit may or may not be peeled but stems and calices should be removed. Canned tomatoes may be packed with or without an added

liquid. Calcium salts varying from 0.045% to 0.08% by weight of the finished products can also be added. Other ingredients such as organic acids, spices, oil, and flavorings can be added up to 10%. There are three categories of canned tomatoes. The label tomatoes are valid only for peeled and canned tomato. Unpeeled tomatoes are labeled accordingly. Stewed tomatoes are canned tomatoes containing onion, celery, and peppers (Anon 1993). The flowchart for the manufacture of canned tomatoes is as follows: Fresh tomatoes → Sorting → Washing → Resorting → Trimming → Peeling → Final Inspection → Cutting (except for whole tomatoes) → Filling → Exhausting → Steaming and Thermal processing. Most of the operations are similar to the ones described for canning in general.

Peeling

Tomatoes for canning are peeled with hot water, steam, or lye. Tomatoes are passed through boiling water bath or live steam chamber for 15–60 seconds, depending on the variety, size, and ripeness of the fruit. The temperature of 98°C or above is recommended. The hotter the water, the shorter is the scalding time. Boiled tomatoes are immediately cooled in cold water and then peeled by hand or with a machine. Hand peeling is labor intensive and is completed by removing the core with a knife. Machine peeling is faster and is done by scrubbing or cutting and squeezing. For lye treatment, a solution of hot 14–20% soda caustic (sodium hydroxide-NaOH) is normally used in two ways. Tomatoes could be immersed in the solution or sprayed. Then, a scrubber removes the disintegrated skins. Lye peeling is less labor intensive, but uses more water than hot water and steam peeling. Since the peeled tomatoes are thoroughly rinsed to remove the residual lye, treatment with up to 10% of citric acid is recommended. Lye treatment creates more pollutants, and loss of soluble solids compared to the other two methods.

Inspection

The final inspection after peeling is very important for the grading of the finished product. Canned tomatoes are graded in categories, A, B, C or 1st, 2nd, or 3rd class product. The purpose of the final inspection is to remove any visible defects in the products including residual peel fragments, extraneous vegetable materials, as well as checking the wholeness (when necessary).

Cutting

Peeled tomato may be cut into halves, slices, dices, wedges when necessary, using cutter, slicer, or dicer before filling in the can.

Filling

Filling of tomato in cans can be done by hand or by machine. The best quality whole tomatoes are filled by hand and filled up with tomato juice. Softening during heating can be avoided by addition of calcium chloride or calcium sulfate, in the form of tablets or mixed in tomato juice and dispensed in each can. In order to inhibit the action of *C. botulinum*, a required pH less than 4.6 is secured by the addition of citric acid in the form of tablets in each can. For stewed tomato, 3/4 filled cans with peeled tomatoes are spiced with dehydrated onion, garlic, chopped celery, green bell pepper dices, as well as tablets made of citric acid and a mixture of salt, sugar, and calcium chloride into the can. The can is then filled up with tomato juice until an acceptable level of headspace is reached.

Exhausting

The purpose of exhausting is to create enough vacuum in the can, in order to avoid fast deterioration of the canned product during the summer season. A minimum temperature of 71°C at the center of a can after the completion of exhaust is recommended (Luh and Kean 1988). Exhaust is normally done in steam chambers. The exhaust time in the chamber depends on the size of the can and varies from 3 minutes for 300 mm × 407 mm to 10 minutes for 603 mm × 700 mm cans. Exhaust is also done by mechanical vacuum closing machines (Lopez 1987, Gould 1992).

Processing Time of Canned Tomatoes

The processing time of canned tomato depends on many factors including the pH of the canned tomato, the major spoilage microorganisms of concern, the size of the can, and the type of retort (sterilizer). Organisms of concern in canned tomatoes are *Clostridium pasteurianum* and *Clostridium butyricum*, as well as *Bacillus coagulans* (*Bacillus thermoacidurans*). Spores of butyric acid anaerobes are destroyed at 93.3°C for 10 minutes when the pH is higher than 4.3, and after 5 minutes, when the pH is between 4 and 4.3. Canned tomatoes can be processed with a rotary sterilizer, a conventional stationary retort or in an open nonagitating cooker. In general, the processing time is longer if the cooling is done by air instead of with water. For a rotary sterilizer the processing time at 100°C for a can of 307 mm × 409 mm may be reduced by 9 minutes or shorter if air cooled, and by 13 minutes or shorter if water cooled. For the same size of can at 100°C an open nonagitating cooker or a conventional retort would require a processing time of 35–55 minutes. The can center temperature should reach 82°C, when air cooled, and 90°C when water cooled (Lopez 1987). The retort time depends on the size of the can, the fill weight, and the initial temperature of the canned product.

TOMATO JUICE PROCESSING

Processing

Tomato juice is defined as the unconcentrated, pasteurized liquid containing a substantial portion of fine tomato pulp extracted from good quality, ripe, whole tomatoes from which all stems and unnecessary portions have been removed by any method that does not increase the water content, and may contain salt and a sweetening ingredient in dry form (Canadian Food and Drugs Act). Only high-quality tomatoes should be used for juice production. Tomatoes are important source of vitamins A and

C, and antioxidants such as lycopene. In tomato and tomato products, color serves as a measure of total quality. Consumers notice color first and their observation often supplements preconceived ideas about other quality attributes such as aroma and flavor. Color in tomato is due to carotenoids, a class of isoprenoid compounds varying from yellow to red color. Most carotenoids are tetraterpenes (C-40), derived from 2 C-20 isoprene units (Geranylgeranyl pyrophosphate). The most isolated and quantified carotenoids in tomato and tomato products include lycopene, lycope-5–6-diol, α-carotene, β-carotene, γ-carotene, δ-carotene, lutein, xanthophylls (carotenol), neurosporene, phytoene, and phytofluene. Lycopene is the major carotenoid of tomato and comprises about 83% of the total pigments present in the ripe fruit (Thakur et al. 1996). Therefore, the levels of lycopene are very important in determining the quality of processed tomato products. Not only does it determine the color of tomato products, but also provides antioxidant properties to it. Lycopene is considered as a preventive agent against coronary heart disease and cancers (Gerster 1991, Clinton 1998). The flowchart for making tomato juice is as follows: Fresh tomatoes → Washing → Sorting and Trimming → Comminution → Extraction → Deaeration → Homogenization → Salting and Acidification → Thermal Processing → Tomato juice.

Comminution

Comminution is a process of chopping or crushing tomatoes into small particles prior to extraction. The comminuted tomatoes are subjected to either cold-break or to hot-break processing. The cold-break processing produces tomato juice with a more natural color, fresh flavor, and higher vitamin C content than does hot-break process. The hot-break process on the other hand, produces tomato juice with higher consistency, lesser tendency to separate, but with a cooked flavor. During the cold-break process, the comminuted tomato is heated below 65°C to introduce rapid enzyme inactivation, and held at room temperature for a short time (a few seconds to many minutes), prior to extraction. In the hot-break process, the tomatoes are rapidly heated to above 82°C, immediately following comminution, in order to inactivate pectinesterase and enhance pectin extraction. Hot-break process can be done either in a rotary heat exchanger or in a rotary coil tank. The latter not only inactivates the enzymes fast enough to retain most of the serum viscosity, but also deaerates the juice. Low pH inhibits pectic enzymes and enhances the extraction of macromolecules such as pectin. Therefore, the addition of citric acid to the juice during comminution improves the consistency of the juice (Miers et al. 1970, Becker et al. 1972).

Extraction

Extraction is a process of separating the seeds and skins from the juice. There are two types of extractors: screw type and paddle type. The screw-type presses tomatoes between a screw and a screen with about 0.5–0.8 mm (Lopez 1987). Paddle-type extractors beat the tomato against screens. The extraction yields 3% of seeds and skins and 97% juice. Procedures that target a lower yield of 70–80% result in a better quality juice and a high quality residue for other purposes.

Deaeration

The deaeration process improves color, flavor, and ascorbic acid content of the juice. It is done immediately after the extraction by a vacuum deaerator. Removal of oxygen inhibits oxidative processes.

Homogenization

A stable juice is one in which the solid and liquid phases do not separate during storage for a long period of time. The ability of a juice to separate depends on many factors including the serum viscosity, the gross viscosity, the pH of the medium, the size and shape of the suspended solids and so on. Homogenization is a process of forcing the juice through narrow orifices at a pressure of 6.9–9.7 MPa and a temperature of about 65°C to break up the suspended particles to a fine consistency (Lopez 1987).

Salting

Sodium chloride is sometimes added to the juice at a rate of 0.5–1.25% by weight in order to improve the taste of the tomato juice. Citric acid is added to improve the color, flavor, and taste. In addition, citric acid inhibits polyphenoloxidase by removing the bound copper from the enzyme, reducing browning reactions and improving color.

Quality Attributes of Tomato and Processed Products

The major quality attribute of ripe tomato is its red color, which is due to the lycopene content of the fruit. Other important physicochemical parameters, which determine the quality of tomato are Brix, acidity, pH, vitamin C, ash, dry matter, firmness, fruit weight, and flavor volatiles. For processed tomato product, the required quality attributes are precipitate weight ratio, serum viscosity, total viscosity (Brookfield), and lycopene content of the product. Several quality attributes of tomato and tomato products can be improved by genetic modification of tomatoes (Oke et al. 2003). These comparisons were made between fruits obtained from untransformed and genetically transformed tomato plants carrying an antisense phospholipase D cDNA, and juice prepared from these fruits. The levels and activity of phospholipase D, the key enzyme involved in membrane lipid degradation, were considerably reduced by antisense transformation. These changes potentially resulted in increased membrane stability and function that also improved several quality parameters. The flavor profiles of blended antisense tomato fruits were different from the controls, being enriched in volatile aldehydes such as pentenal and hexenal. Increased membrane stability in transgenic fruits potentially resulted in lowered degradation of unsaturated fatty acids such as linoleic and linolenic acids and may have contributed to increased substrate availability for lipoxygenase pathway enzymes (lipoxygenase, hydroperoxide lyase, and so on) during blending with an increased evolution of volatile

Table 29.8. Physicochemical Parameters of Tomato Fruits and Processed Juice from Transgenic and Control Tomato

Properties	Control	Transgenic
Fruit weight (g)	95.14 ± 36.56^a	34.87 ± 21.57^b
Firmness (N)	4.97 ± 0.59^a	5.99 ± 1.03^b
Redness (a+)	29.6 ± 0.70^a	31.70 ± 1.67^a
Acidity (%)	0.36 ± 0.00^a	0.38 ± 0.05^a
Brix	4.55 ± 0.71^a	4.75 ± 0.71^b
Dry matter-NSS (%)	3.54 ± 0.05^a	5.15 ± 0.03^b
Ash (%)	0.63 ± 0.03^a	0.089 ± 0.13^b
Vitamin C (mg/100g)	3.9 ± 0.00^a	10.4 ± 0.016^b
PPT (%)	15.70 ± 0.33^a	16.17 ± 0.48^a
Serum viscosity (mpa·s)	1.0919 ± 0.04^a	1.2503 ± 0.010^b
Brookfield viscosity (mpa·s)	1075 ± 35^a	1400 ± 35^b
Lycopene (mg/100g)	11.73 ± 2.10^a	17.47 ± 0.58^b

[a,b]The values showing different superscripts are significantly different at $P < 0.05$.

aldehydes. Table 29.8 provides a comparison of various quality parameters between a genetically modified tomato and a control, which shows improvements in several quality parameters due to the transformation.

PHYSICOCHEMICAL STABILITY OF JUICES

There are two categories of juices, clear and comminuted. Clear juice such as apple juice contains no visible vegetal particles, whereas a comminuted juice such as tomato juice contains mostly vegetal particles suspended in a liquid. To be stable, a clear juice needs to remain clear (without sediment) during its shelf life. On the other hand, a comminuted juice may not separate into distinct phases during the shelf life of the product. An important quality attribute of juices such as tomato juice is the stability of their disperse system. In order to be stable, a juice needs to be kinetically and physically stable.

Kinetic Stability

The ability of a poly-disperse system containing suspended particles to maintain its homogenous distribution without agglomeration is called kinetic or sedimentation stability. Kinetic stability depends on many factors, the most important of which include size of suspended vegetable particles, viscosity of the disperse medium and the intensity of the Brownian motion. In a liquid medium, heavier or larger particles sediment faster than the lighter ones in response to gravity. The sedimentation velocity of any particle is described by the following Stokes Equation:

$$V = 2/9 r^2 (\rho 1 - \rho 2)(1/\eta)g \tag{2}$$

where V is the sedimentation velocity, m/s (meter/second); r is the radius of the suspended particles (m); $\rho 1$ and $\rho 2$ are the densities of the particles and the serum, respectively (kg/m³; serum = liquid medium in which particles are suspended);

Table 29.9. Sedimentation of Spherical Mineral Particles in Water and in Juice With a Depth of 1 cm

Particle Size (μ)	Velocity (m/s)	Sedimentation Time in Water	Sedimentation Time in Juice
10	3.223×10^{-4}	31.03 s	2.29 min
0.1	3.223×10^{-8}	86.2 h	16 d
0.001	3.223×10^{-12}	100 yrs	436 yrs

η is the viscosity of the juice (Pa·s; Pascal·second); and g is the gravitational force (g = 9.81 m/s²; meter/second²).

The sedimentation time of a given particle is about 4 times longer in a juice than in water (Table 29.9.).

Particles larger than 10 μm will sediment in a few seconds. This is the reason why the sedimentation stability of juices, especially comminuted juices such as tomato juice is a serious processing issue.

The physical force that affects the sedimentation of particles in a juice is called normal force and can be calculated by:

$$f' = mg, \tag{3}$$

where m is the mass (kg) of the suspended particle. In general, a particle with a spherical shape has a mass represented by:

$$m = 4/3 \pi r^3 \rho 1 \tag{4}$$

where $\pi = 3.14$, r is the radius of the particle and $\rho 1$ is the density of the particle. For particles with nonspherical shape (most of suspended particles), r is equal to the nearest equivalent value of a spherical particle with an identical mass and an identical density.

During particle sedimentation, another important force, friction, also comes into play. Friction between particles results in a reduction in their movement.

The frictional force $f'' = 6\pi \rho\, rv$ (5)

where η is the viscosity of the medium; r is the radius of the particle in meters; and v is the velocity of the particle (m/s).

Friction between the particles increases depending on the density of the medium, higher the density, higher the friction. When $f' = f''$, sedimentation of the particles occur.

Kinetic stability of a heterogeneous dispersion system also depends on Brownian motion. The most dispersed particles have a very complex motion due to collisions from molecules in the dispersed medium. Because of this, the suspended particles are subjected to constant changes in their velocity and trajectory. Molecular kinetics shows that dispersed particles with colloidal size change their path 10^{20} times/second. These particles may also acquire a rotational Brownian motion. This is why colloidal particles have higher sedimentation stability than larger particles. With an increase in the mass of the suspended particles, their momentum also increases. Particles smaller than 5×10^{-4} cm in diameter that oscillate around a point do not sediment, whereas larger particles that do not experience as much Brownian motion as smaller particles easily sediment. Thus, when particles have reduced motion, they tend to aggregate

and enhance sedimentation. Under ideal conditions, obtaining a colloidal particle size will enhance the stability of a juice preparation.

Physical Stability

Physical stability results from the property of a polydisperse system that inhibits the agglomeration of suspended particles. In a system with low physical stability, suspended particles agglomerate to form heavier particles ($> 5 \times 10^{-4}$ cm in diameter) that easily sediment. Physical stability depends on two opposing forces, attracting and repulsing forces.

Attracting forces between molecules are referred to as van der Vaals forces, which reduce the physical stability of heterogeneous colloidal system. The intensity of attractive forces increases as the distance between suspended particles decreases.

Repulsing forces between particles are caused by the charges surrounding the particles designated by their ζ- potential. When ζ-potential is zero, the net charge surrounding the particle is also zero, and the suspended particles are said to be at their isoelectric point. Agglomeration of particles begins at a given value of ζ-potential called as the critical potential. This is the point at which equilibrium is reached between van der Vaals forces (attraction) and repulsing forces. Different heterogeneous colloidal disperse systems have different values of critical potential. When the ζ-potential (repulsive forces) of a particle is higher than the critical potential, hydrophilic colloids are stable due to the repulsion between particles, whereas at a lower potential than the critical potential ζ, the particles tend to aggregate. The effective energy of interaction between particles of a heterogeneous colloidal system is expressed by:

$$E = E_A + E_R, \tag{6}$$

where E_A is the attracting energy, and E_R is the repulsing energy.

Attracting energy is actually the integration of the sum of all attracting forces between molecules of two colloidal particles. For two particles with radius r, the potential energy is expressed by:

$$E_A = -Ar/12h \tag{7}$$

where, h is the distance between surfaces of the two particles, and A is the Hamaker constant (10^{-1}–10^{-21} J). Consequently, attracting forces decrease as the distance between particles increase.

On the other hand, particles can come closer to one another up to a certain distance after which they start repulsing each other because of their ζ-potential. When two particles are very close, their similar ionic charge (positive or negative) layers create a repulsive force, which keeps them apart. The repulsing energy between two particles with the same radius r and the same surface potential Ψ_0 is expressed by:

$$E_R = -2 \int \Delta P \, d\delta, \tag{8}$$

where ΔP is the increase in osmotic pressure; δ is thickness of the double ionic layer; and the number 2 relates to the energy changes between 2 particles.

$$\Delta P = \Delta n K T \tag{9}$$

where Δn is the increase in the ionic charge between the 2 particles; K is the Boltzman's constant; and T is the temperature in degrees Kelvin ($^\circ$K).

Assuming that the two particles are spherical, the formula (8) can be expressed by:

$$ER \approx \left[\left(\varepsilon r \psi_0^2 \exp\{-\chi h\}\right)\right]/2, \tag{10}$$

where ε is the dielectric constant; r is the radius of particles; h is the distance between the two particles; ψ_0 is the surface potential, and χ is a constant which characterizes the double ionic layer.

The inferences from the Equation 10 are that:

1. repulsing energy exponentially decreases as the distance between the particles increases; and
2. repulsing energy quadratically increases as the surface potential increases and as the radius linearly increases.

For particles with radius r and a constant surface potential, E_R depends on χ. Figure 29.2 shows the interaction between two particles (1 and 2) under constantly increasing χ. As a result of decreasing the thickness of the double ionic layer and a decrease in ζ-potential, the distance between the two particles decreases
Figure 29.2. Interactive energy between two particles.

leading to an increase in the repulsing energy according to the Equation (10). For a given h, the residual energy reaches the maximum value (E_{max}), which must be overcome by particle 1 in order to aggregate with particle 2. Continual increase of χ and a decrease in the distance between particles h reduces the effect of repulsing energy E_R over the residual energy E ($E_R - E_A$ or E_{max}), which reaches its minimal value M. At this stage, the attracting energy E_A dominates and the particles aggregate. The speed of aggregation is an important physicochemical parameter for the stability of a microheterogeneous system. E_{max} is called coagulation energy and determines the speed of aggregation. When $E_{max} > 0$ (Fig. 29.2A), the aggregation process is slow, whereas when $E_{max} < 0$ (Fig. 29.2B) the process is quick, since the particles of the system do not have to overcome E_{max} (When $E_A > E_R$, $E_R - E_A$ is <0, Fig. 29.2A, B). The critical concentration of coagulation is reached at $E_{max} = 0$, when both the attractive and repulsive energies are equal.

In a real situation of polydisperse colloidal system such as juice, suspended particles have different sizes and different ψ_0 and ζ- potential. When two particles with different sizes and different surface ζ- potential approach each other, an opposite charge is induced upon the particle with lower ζ- potential, which activates the agglomeration. Another important factor in the stability of juices is the hydrated layer of suspended colloidal particles. The formation of hydrated layer is due to the orientation of water molecules towards the hydrophilic groups such as -COOH, -OH, and so on situated on the surface of the particles. A decrease in ζ- potential leads to a decrease in the hydrated layer of suspended particles, and therefore, increases the susceptibility to aggregation. The ability of the hydrated layer to increase stability is explained by Deryagin theory, which stipulates that when suspended particles are in close proximity, their hydrated layers are reduced, leading to an increase in repulsive forces between them. Only strong hydrated layers can affect the aggregative stability of a polydisperse system. The probability of the formation of such hydrated layers around vegetal particles in juices is very low, because of the weak energetic relationship between the particles and the disperse phase. In this case, hydrated layers play a secondary role to supplement the action of the double ionic layer.

Stability from particular aggregation in juice is also influenced by the viscosity of the disperse medium. The viscosity of the disperse phase or serum of juices is mainly composed of high molecular mass compounds such as pectin, protein, and starch. Practically, this is achieved by the addition of such compound to the juice. The mechanism of action is as follows. Upon addition of high molecular mass compounds (pectin), they adsorb on the surface of the hydrophobic vegetal particles to make a layer of hydrophilic molecules, circled by a thick hydrated layer, which gradually blends into the disperse medium. Pectin is the stabilizer of choice in the juice processing industry, compared to protein and starch. With an increase in the concentration of high molecular mass compounds, the sedimentation stability of the juice increases. It has been established that with the increase in the concentration of pectin in the juice, the stability increases to reach a plateau after which, a further increase does not provide an added beneficial effect (Idrissou 1992).

The mechanism of the sedimentation stability of the juice is as follows:

- Low adsorption velocity: Lower adsorption velocity is observed under lower concentration of stabilizers.
- Irreversible adsorption: Stabilizers in most cases are bonded to the particular phase surface with strong adsorption bonds.
- Adsorption is described by the curve in Figure 29.3, following a typical saturation curve.
- Different configuration of adsorption by particles is shown in Figure 29.3. Molecules of linear polymers can be adsorbed in three different ways, depending on their affinity to the liquid phase and the surface of the suspended particles, adopting horizontal, vertical, and stitchlike configurations.

Enhancing Nutraceutical Quality of Juice Products

Health beneficial effects of enhanced fruit and vegetable consumption through enhanced intake of nutraceuticals (functional food ingredients) are well established. There are several types of juice blends from fruits and vegetables available in the market including those that are blends of fruits and vegetables. An additional way of enhancing the nutraceutical value of various juices is by the addition of specific ingredients. In a recent study, Oke et al. (2010) have described the benefits of adding soy lecithin to tomato juice and sauce preparations and its effect on stability characteristics of the juice and sauce. Soy lecithin is enriched in proteins as well as lipids such as phosphatidylcholine, a key component in the biomembrane. Choline is also a key component of nervous system function linked to the biosynthesis of acetyl choline, involved in nerve signal transmission, lipid secretion, enhancement in liver function, and so on. Juice/sauce preparations from fruits and vegetables are generally low in phospholipids. Thus, addition of soy lecithin to juice could be beneficial both in terms of nutrition and stability of juice. Addition of 0.5–1% (w/v) soy lecithin to tomato juice and sauce enhanced the stability characteristics of the processed products such as precipitate weight ratio and Brookfield viscosity. Commercially, soy lecithin is not added to juice or sauce preparations at present.

MINIMALLY PROCESSED VEGETABLES

Definitions

Rolle and Chism (1987) defined minimally processed refrigerated fruit and vegetable (MPR F & V) as produce which have undergone minimal processing such as washing, sorting, peeling, slicing, or shredding prior to packaging and sale to consumers. Odumeru et al. (1997, 1999) defined ready-to-use vegetables as fresh-cut, packaged vegetables requiring minimal or no processing prior to consumption. It is generally accepted that MPR F & V are products that contain live tissues or those that have been only slightly modified from the fresh condition and are freshlike in character and quality.

Adsorption state of polymers

(A) Horizontal (B) Vertical (C) Stichlike
Figure 29.3. Isotherm of adsorption of polymers; polymer adsorption states.

The rapid growth of fast-food restaurants in the 1980s encouraged the development and use of fresh-cut products. As the demand for products increased, new technology and product innovation were developed to help make fresh-cut produce, one of the fastest growing segments of the food industry. It is estimated that in the US fresh-cut produce market, up to 8% of all produce is sold in retail grocery outlets and 20% sold in the food service industry. It is expected to continue growing in size and popularity as more products are introduced and consumers change their buying habits. In the first quarter of 2006, the sale of fresh cut produce in the United States accounted for $1.3 billion, with major sales (∼80%) coming from vegetables. In 2007, the fresh cut produce market was estimated at $15.9 billion in the United States (www.agecon.ucdavis.edu). Freshly prepared ready to eat salads, now with cut tomatoes, will have a shelf life of up to 14 days utilizing unique Modified Atmosphere Packaging technology.

PROCESSING

The major operations in processing of MPR produce include Sorting/Sizing/Grading, Cleaning/washing/disinfection, Centrifugation, and Packaging and Distribution. For certain vegetables such as eggplant, the peeling operation follows the sorting operation that results in a size reduction, and mixing, packaging and distribution. Washing of vegetables for minimal processing, uses a significant amount of water (5–10 L/kg) to achieve a reduction in the bacterial load. The main pathogen of concern in this type of products is *Listeria monocytogenes*. The water temperature of about 4°C is recommended. The safety of the product is best secured through disinfection with chlorine at a concentration of about 100 mg/L. Two forms of chlorine are commonly used: gaseous chlorine, which is 100% active chlorine, and calcium or sodium hypochlorites. The latter is most popular in MPR industry.

Centrifugation is one of the major operations in MPR processing. The purpose is to dry the vegetables rapidly. The efficacy of the centrifugation depends on the speed and time of rotation of the centrifuge. Certain antioxidants such as ascorbic acid and citric acid at a concentration of about 300 ppm in the wash solution would enhance the quality of the products. The processing techniques employed usually wound the tissue and may cause the liberation of "wound ethylene" that can activate deteriorative reactions within the tissue. Vegetables of high quality may also have a good complement of the antioxidants (vitamins C and E, reduced glutathione) and the antioxidant enzyme system that comprise the enzymes such as superoxide dismutase, catalase, peroxidase, ascorbate peroxidase, and so on. An active pentose phosphate pathway is required for the supply of reduced nicotinamide adenine dinucleotide phosphate-reduced form for the efficient functioning of the antioxidant enzyme system. Membrane phospholipid degradation mediated by phospholipase D, is activated in response to wounding the tissue. Damage to the tissue during processing can cause the leakage of ions such as Ca^{2+} and H^+ which can activate phospholipase D. Naturally occurring phospholipase D inhibitors such as hexanal can be used to reduce the activity of phospholipase D in processed tissues and enhance their shelf life and quality (Paliyath et al.

2003). The quality of MPR F & V can be increased by following Good Manufacturing Practices, the main points of which are: minimizing handling frequency, providing continued control of temperature, the relative humidity (% RH), modified atmosphere and controlled atmosphere (MA/CA storage etc.). The product is always transferred from truck to refrigerated storage immediately to minimize degradative and oxidative reactions. The products are replaced on a first-in/first-out basis, and the inventory on a weekly basis. Currently MPR include the following items: ready-to-eat fruits and vegetables, ready-to-cook fruits and vegetables, ready-to-cook mixed meals, and fresh ready-to-use herbs and sprouts.

QUALITY OF MPR

Consumers expect fresh-cut products to be of optimum maturity, without defects, and in fresh condition. The most important physicochemical quality parameters targeted for preservation include good appearance, nutrients, and excellent sensory attributes such as texture, firmness, and taste. Minimally processed products are vulnerable to discoloration because of damaged cells and tissues that become dehydrated. Cutting and slicing of carrots with a very sharp blade reduces the amount of damaged cells and dehydration, when compared with those sliced with a regular culinary knife. To overcome the problem with dehydration, fresh-cut produce can be treated with calcium chloride and kept in a high humidity atmosphere. Enzymatic browning is a serious problem with minimally processed produce. During the processing of produce, several types of oxidative reactions may occur, leading to the formation of oxidized products. These reactions cause browning reactions resulting in the loss of nutritional value by the destruction of vitamins and essential fatty acids. In lipid-rich vegetables, oxidative processes lead to the development of rancid off-flavors and sometimes to toxic oxidative products (Dziezak 1986). There are a number of chemicals used to stabilize MPR produce including: (a) free radical scavengers such as tocopherols; (b) reducing agents and oxygen scavengers such as ascorbic acid and erythorbic acid; (c) chelating agents such as citric acid, and (d) other secondary antioxidants such as carotenoids. Ascorbic acid is commonly used either alone, or in combination with other organic acids. Temperature is the most important factor that influences the general quality of MPR produce. When temperature increases from $0°C$ to $10°C$, respiration rate increases substantially, with Q_{10} (fold increase in respiration by a $10°C$ increase in temperature) ranging from 3.4 to 8.3 among various fresh-cut products. With the increase in respiration rate, deterioration rate also increases at a comparable rate; therefore, low temperature storage is essential for maintaining good quality (Watada et al. 1996). MA within MPR container or bags is useful in keeping the quality of the produce (Gorny 1997). Gas mixtures suitable for MA storage have been the same as those recommended for the whole commodity (Saltveit 1997). CA system is used to simulate the MA with similar gas composition. A mixture of 10% O_2 + 10% CO_2 has been shown to retard chlorophyll degradation in parsley and broccoli florets (Yamauchi and Watada 1993, 1998). An atmosphere of 3% O_2 + 10% CO_2 was beneficial for fresh-cut iceberg lettuce, slightly

beneficial for romaine lettuce, and not beneficial for butterhead lettuce (Lopez-Galvez et al. 1996). The oxygen level can be allowed to drop to the level of respiratory quotient breakpoint. The O_2 level could be dropped to 0.25% for zucchini slices (Izumi et al. 1996), and 0.8% for spinach (Ko et al. 1996). Other technologies that involve inactivation of ethylene action using 1-Methylcyclopropene (Lurie and Paliyath 2008), or controlling gas movements using edible coating technologies (Fallik 2008) are also being employed increasingly.

Non-Enzymatic Browning in Cookies, Crackers and Breakfast Cereals

A.C. Soria and M. Villamiel

Abstract: In this chapter, the authors have attempted to collect the main studies carried out up to 2010 on the most investigated quality indicators in cookies, crackers and breakfast cereals. These cereal-based foods, mainly consumed for breakfast, constitute a very important source of energy, particularly in the case of children. For this reason, their processing (baking or extrusion cooking) should be carefully carried out in order to keep their quality. One of the main reactions that takes place during the processing of these cereal-based foods is non-enzymatic browning including Maillard reaction and caramelisation, which might contribute to the development of colour and fluorescence. In this sense, the evaluation of chemical indicators such as available lysine, furosine, hydroxymethylfurfural, furfural, acrylamide and maltulose might afford important information on the processing and storage conditions to which cereal-based products have been submitted.

INTRODUCTION

Cereal-based products such as cookies, crackers and breakfast cereals represent a predominant source of energy in the human diet, especially for children consuming cereal derivatives for breakfast meals.

Cookies, crackers and breakfast cereals can be manufactured by means of traditional processes or by extrusion cooking. In general, during conventional treatment of flour products (usu-ally, temperatures higher than 200°C for several minutes), more intense processing conditions are applied as compared to those used in the extrusion process (González-Galán et al. 1991, Manzaneque Ramos 1994, Huang 1998).

Extrusion cooking is a well-established industrial technology with a number of food applications since, in addition to the usual benefits of heat processing, extrusion has the possibility of changing the functional properties of food ingredients and/or of texturising them (Cheftel 1986). In the extruder, the mixture of ingredients is subjected to intense mechanical shear through the action of one or two rotating screws. The cooking can occur at high temperatures (up to 250°C), relatively short residence times (1–2 minutes), high pressures (up to 25 MPa), intense shear forces (100 rpm) and low moisture conditions (below 30%). In addition to the cooking step, cookies, crackers and breakfast cereals manufacture involves toasting and/or drying operations (Cheftel 1986, Camire and Belbez 1996, Manley 2000).

During these technological treatments, due to the elevated temperatures and low moisture conditions used, different chemical reactions such as the non-enzymatic browning can take place. Non-enzymatic browning includes Maillard reaction (MR) and caramelisation. The products resulting from both reactions depend on food composition, temperature, water activity and pH, and can occur simultaneously (Zanoni et al. 1995).

As it is known, MR occurs between reducing sugars such as glucose, fructose, lactose or maltose, and free amino groups of amino acids or proteins (usually the ε-amino group of lysine). The MR is favoured in foods with high protein and reducing carbohydrate content at intermediate moisture content, temperatures above 50°C and a pH in the range from 4 to 7. Caramelisation depends on direct degradation of carbohydrates due to heat and it needs more drastic conditions than those of the MR. Thus, at temperatures higher than 120°C, pH lower than 3 or higher than 9 and very low moisture content, caramelisation is favoured (Kroh 1994).

Furthermore, other chemical reactions that might take place during processing of these products may also affect the extent of non-enzymatic browning. Thus, starch and non-reducing sugars such as sucrose can be hydrolysed into reducing sugars that can later be involved in other reactions, for instance, in the MR (Camire et al. 1990).

The chemical changes that take place during the technological process used in the elaboration of this type of cereal-based foods contribute, to a certain extent, to their typical organoleptic characteristics. However, important losses of lysine due to the formation of chemically stable and nutritionally unavailable derivatives of protein-bound lysine can be observed under MR conditions (Torbatinejad et al. 2005).

The amount of lysine and its biological availability are meaningful criteria for the nutritive quality of cereals, as foods processed from cereal grains are low in essential amino acids such as lysine and methionine (Horvatić and Eres 2002). As this deficiency can be further impaired by losses originated in browning reactions during processing, a compromise must be found where the objectives of heat treatment are reached with a minimal decrease in the nutritional quality of the food. Different indicators based on the evaluation of the extent of non-enzymatic browning have proved to be useful, not only for processing control, but for optimisation of operating conditions in the manufacture of cereal-based foods (Singh et al. 2000, Gökmen et al. 2008a, 2008b). Although some of the studies on cereal-based products reported in this review have not been directly carried out in cookies, crackers or breakfast cereals, they have been considered here since both the manufacture and composition could be similar and, consequently, the same chemical reactions might be involved.

NON-ENZYMATIC BROWNING INDICATORS

Available Lysine

The determination of available lysine has been used to evaluate the effect of heating on the protein quality of the following cereal-based products: pasta (Nepal-Sing and Chauhan 1989, Acquistucci and Quattrucci 1993), bread (Tsen et al. 1983, Ramírez-Jiménez et al. 2001), cereals (Fernández-Artigas et al. 1999a), cookies fortified with oilseed flours (Martinkus et al. 1977) and biscuits (Singh et al. 2000).

Since extrusion cooking is a well-established technology for the industrial elaboration of cereal-based foods, several authors have studied the effect of the initial composition and the different operating conditions on lysine loss in extruded materials. In samples of protein-enriched biscuits, Noguchi et al. (1982) found that the loss of reactive lysine is significant (up to 40% of the initial value) when the extrusion cooking is carried out at high temperature (190–210°C) with a relatively low water content (13%). When moisture is increased to 18%, the lysine loss is much less pronounced or even negligible.

Noguchi et al. (1982) also studied the effect of the decrease of pH on lysine loss in biscuits obtained by extrusion. These authors observed a higher lysine loss at low pH, since strong acid-

ification markedly increases starch or sucrose hydrolysis and, consequently, the formation of reducing carbohydrates. Starch hydrolysis and corresponding formation of reducing sugars was also proposed as the main cause of lysine loss in extruded wheat flours (Bjorck et al. 1984).

An important decrease of available lysine content (40.9–69.2%) in wheat grain processed by flaking and toasting was observed by McAuley et al. (1987), and they attributed these results to the high temperature reached during toasting. In general, extrusion cooking of cereal-based foods appears to cause lysine losses that do not exceed those for other methods of food processing. In order to keep lysine losses within low levels (10–15%), it is necessary to avoid operating conditions above 180°C at water contents below 15% (even if a subsequent drying step is then necessary) (Cheftel 1986).

Phillips (1988) suggested that the MR is more likely to occur in expanded snack foods in which nutritional quality is not a major factor than in other extruded foods with higher moisture contents, if the processing conditions are controlled. Horvatić and Guterman (1997), in a study on the available lysine content during industrial cereal (wheat, rye, barley and oat) flake production, found that the effects of particular processing phases can result in a significant decrease of available lysine amounts in rye and oat flakes, whereas less influence can be observed in the case of wheat and barley flakes. Apart from the importance of processing conditions, the results obtained by these authors seem to indicate that the decrease of lysine availability is higher for cereals with greater available lysine contents in total proteins.

Other important consideration is to avoid the presence of reducing sugars during extrusion. Lysine loss and browning are more intense when reducing carbohydrates such as glucose, fructose or lactose (added as skim milk) are added to the food mix above 2–5% level (Cheftel et al. 1981). In agreement with these results, Singh et al. (2000) and Awasthi and Yadav (2000) found higher lysine loss and browning in traditionally elaborated biscuits enriched with whey or skim milk.

An investigation of the changes in available lysine content during industrial production of dietetic biscuits was performed by Horvatić and Eres (2002). Dough preparation did not significantly affect the available lysine content. However, after baking, a significant loss (27–47%) of available lysine was observed in the studied biscuits. The loss of available lysine was found to be significantly correlated with technological parameters, mainly baking temperature/time conditions.

The influence of storage on the lysine loss in protein-enriched biscuits was studied by Noguchi et al. (1982). Lysine loss was observed to increase when samples were stored at room temperature for a long period of time. Hozova et al. (1997) estimated, by measurement of lysine, the nutritional quality of amaranth biscuits and crackers stored during 4 months under laboratory conditions (20°C and 62% RH). Although a slight decrease in the level of lysine was detected, this was not significant. However, these authors suggested that lysine degradation can continue with prolonged storage and it is necessary to consider this fact in relation to consumers and the extension of storage time.

In a survey on 20 commercially available cereal-based breakfast foods, Torbatinejad et al. (2005) stated that reactive lysine

is a more accurate measure of unmodified lysine since total ly-
sine determination often includes lysine that has reverted from
modified lysine derivatives (early Maillard products) during
acid hydrolysis. In addition to the formation of unavailable ly-
sine derivatives, it has also been described that the advance
of MR as a result of processing is at least partly responsible
for the reduction in the overall protein digestibility (Rutherfurd
et al. 2006).

FUROSINE

The determination of furosine (ε-N-2-furoylmethyl-lysine), gen-
erated from the acid hydrolysis of Amadori compounds formed
during the early stages of MR (Erbersdobler and Hupe 1991),
has been used for the assessment of lysine loss in malt
(Molnár-Perl et al. 1986), pasta (Resmini and Pellegrino 1991,
García-Baños et al. 2004, Gallegos-Infante et al. 2010), baby
cereals (Guerra-Hernández and Corzo 1996, Guerra-Hernández
et al. 1999), baby biscuits (Carratù et al. 1993), cookies
(Gökmen et al. 2008a), fibre-enriched breakfast cereals
(Delgado-Andrade et al. 2007), flours employed for the for-
mulation of cereal-based products (Rufián-Henares et al. 2009)
and bread (Ramírez-Jiménez et al. 2001, Cárdenas-Ruiz et al.
2004). Other 2-furoylmethyl derivatives such as the ones cor-
responding to GABA (2-FM-GABA) have been, among others,
suggested as indicators of the extent of the MR in different veg-
etable products (Del Castillo et al. 2000, Sanz et al. 2000, 2001,
Soria et al. 2009).

Furosine determination was used by Rada-Mendoza et al.
(2004) to evaluate the advance of MR in commercial cookies,
crackers and breakfast cereals. Furosine was detected in all anal-
ysed samples within a wide range of variation: 25–982 (in cook-
ies), 163–751 (in crackers) and 87–1203 (in cereals) mg/100 g
protein. Figure 30.1 illustrates, as an example, the HPLC chro-
matogram of the 2- FM-amino acids of the acid hydrolysate of
a cereal breakfast sample. Besides furosine, these authors found
2-FM-GABA in samples of crackers and breakfast cereals,
which was absent in most cookie samples analysed. The pres-
ence of 2-FM-GABA in breakfast cereals and crackers may be
attributed to the considerable amount of free GABA present in
rice and corn used in their manufacture.

Recently, Delgado-Andrade et al. (2007) showed that regard-
less of the protein source (i.e., type of cereal), the higher the
protein content, the higher the furosine level of breakfast cereal
formulations. According to this, breakfast cereals enriched in
dietary fibre showed the highest content of this quality marker.
Regarding the physical form of the sample, higher furosine lev-
els were found in puffed cereals as compared to flakes, probably
due to the more pronounced heating during processing.

Contribution of milk components used during breakfast
cereal manufacture to furosine content is still controversial
(Rada-Mendoza et al. 2004, Delgado-Andrade et al. 2007).
Whereas some authors partly attributed the wide variation of
this heat-induced marker to the considerable amounts of furo-
sine in dried milk (Corzo et al. 1994), others concluded that
addition of these components was not directly related to the lev-
els of furosine in the product. The effect of fibre, which was not
taken into account in some of these studies, could be responsible
for the discrepancies observed.

In cookies, furosine formation has been shown to be
highly dependent on the dough formulation and baking con-
ditions (Gökmen et al. 2008a). Therefore, furosine cannot be
Figure 30.1. HPLC chromatogram of the acid hydrolysate of a breakfast cereal sample: (1) 2-furoylmethyl-GABA and (2) furosine (From Rada-Mendoza et al. 2004).

considered a reliable marker of the extent of the thermal treatment for comparison of different products or processing plants. In these cases, the measure of lysine availability is a better index of protein quality.

Similarly, the variable amounts of dried milk used in manufacture of cereal-based products and the different levels of free GABA in unprocessed cereals appear to be the major drawback for the use of furosine and 2-FM-GABA as suitable indicators to differentiate between commercial cereal-based products. However, in the cereal industry, where exact composition is known, measurement of 2-FM-GABA and furosine formed might be used as indicators to monitor processing conditions during the manufacture of cereal products.

Finally, the effect of the addition of common bean flour (15% and 30%) to semolina on furosine content, total phenolics and other parameters related to quality evaluation (moisture, optimal cooking time, cooking loss, water absorption capacity, colour and firmness) was determined by Gallegos-Infante et al. (2010) in spaghetti pasta obtained at different temperatures (60–80°C). Although an increase in furosine and phenolic contents was observed in pasta fortified with bean flour and dried at high temperature, further research is necessary to elucidate the actual phenolic content and the antioxidant capacity related to the MR products or polyphenols.

Hydroxymethylfurfural and Furfural

Hydroxymethylfurfural (HMF) and furfural are intermediate products in the MR, originated from the degradation in acid solution of hexoses and pentoses, respectively (Hodge 1953, Kroh 1994).

HMF is a classic indicator of browning in several foods such as milk (van Boekel and Zia-Ur-Rehman 1987, Morales et al. 1997), juices (Lee and Nagy 1988) and honey (Jeuring and Kuppers 1980, Sanz et al. 2003). HMF has also been detected in several cereal-based foods, including dried pasta (Acquistucci and Bassotti 1992, Resmini et al. 1993), baby cereals (Guerra-Hernández et al. 1992, Fernández-Artigas et al. 1999b), cookies (Ait-Ameur et al. 2006) and bread (Ramírez-Jiménez et al. 2000, Cárdenas-Ruiz et al. 2004).

In a study on the effect of various sugars on the quality of baked cookies, furfural (in cookies elaborated with pentoses) and HMF (in cookies elaborated with hexoses) were detected (Nishibori and Kawakishi 1992). HMF has also been found in model systems of cookies baked at 150°C for 10 minutes (Nishibori and Kawakishi 1995, Nishibori et al. 1998).

García-Villanova et al. (1993) proposed the determination of HMF to control the heating procedure in breakfast cereals as well as in other cereal derivatives. Birlouez-Aragon et al. (2001) detected HMF in commercial samples of breakfast cereals (cornflakes), in samples before and after processing using traditional cooking and roasting, and in a model system of wheat, oats and rice with two levels of sugars submitted to extrusion. Although only traces of HMF were detected in the raw material, HMF formation during extrusion increased proportionally as sugar concentration increased. Among all the analysed samples, the highest content of HMF was found in commercial samples.

The effect of recipe composition in terms of leavening agent (ammonium and sodium bicarbonates) and sugars (sucrose and glucose), and baking conditions (temperature and time) on HMF formation in cookies has been recently studied by Gökmen et al. (2008b). The type of leavening agent, affecting both pH of formulation and degradation of sugars, appeared as one of the most important parameters from the viewpoint of HMF formation. Water activity, which has also been reported to be highly influential on HMF formation, must reach levels lower than 0.4 for allowing a significant formation of this indicator in commercial cookies (Ait-Ameur et al. 2006).

Together with HMF and furfural, glucosylisomaltol (GIM, an intermediate product of the MR that is generated principally from the reaction between maltose and glutamine) has been determined by HPLC as a control index of the MR development in breakfast cereals (Rufián-Henares et al. 2006a), with the advantage over HMF that the MR, and not the addition of thermally damaged ingredients, is the sole pathway of formation of GIM.

Recently, Rufián-Henares and Delgado-Andrade (2009) studied the effect of digestive process on the bioaccessibility of furosine and HMF and on the antioxidant activity of corn-based breakfast cereals. Digestion allowed liberation of HMF and Amadori products (furosine) and increased the solubility of antioxidant compounds.

Colour

Colour is an important characteristic of cereal-based foods and, together with texture and aroma, contributes to consumer preference. Colour is another indication of the extent of MR and caramelisation. The kinetic parameters of these reactions are extremely complex for cereal products. As a consequence, the colouring reaction is always studied globally, without taking into account individual reaction mechanisms (Chevallier et al. 2002). Colour depends both on the physico-chemical characteristics of the raw dough (water content, pH, reducing sugars and amino acid content) and on the operating conditions during processing (Zanoni et al. 1995, Gökmen et al. 2008b).

Brown pigments (melanoidins) formation occurs at the advanced stages of browning reactions and, although is undesirable in milk, fruit juices and tomatoes, among other foods (De Man 1980), it is desirable during the manufacture of cookies, crackers and breakfast cereals. Colour development has been studied in cereal-based foods such as baby cereals (Fernández-Artigas et al. 1999b), bread (Ramírez-Jiménez et al. 2001), cookies (Kane et al. 2003, Gökmen et al. 2008b), breakfast cereals (Rufián-Henares et al. 2006b, Moreau et al. 2009) and gluten-free biscuits (Schober et al. 2003).

The formation of melanoidins and other products of the MR darkens a food, but a darker colour is not always attributed to the presence of these compounds, since the initial composition of the mixture can also afford colour. In a study on the protein nutritional value of extrusion-cooked wheat flours, Bjorck et al. (1984) determined the colour of the extruded material and found a correlation between the reflectance values and total lysine content of extruded wheat. As the reflectance of the raw flours

was very different, comparison could not be made for the effect of extrusion.

Hunter 'L' values determined for wheat flours, commercial flaked-toasted, extruded-toasted, and extruded-puffed breakfast cereals were found to be positively correlated with available lysine (McAuley et al. 1987). Rufián-Henares et al. (2009) concluded that the colour difference (ΔE) obtained from the CIE Lab parameters L∗, a∗, b∗ between toasted and untoasted samples results in a reliable measurement of the visible colour production for the toasting step of different flours usually used for the formulation of cereal-based products. During industrial baking of cookies, the effect of time on colour development and other parameters (volume, structure, weight and crispness) was studied by Piazza and Masi (1997). The development of crispness increased with time and was found to be related to the other physical processes that occur during baking. Gallagher et al. (2003) observed different colour development in the production of a functional low-fat and low-sugar biscuit, depending upon the quantities of sugar and protein present. Regarding spaghetti pasta fortified with different levels of Mexican common bean flour, the difference in colour was associated with the use of common flour rather than the drying temperature assayed (Gallegos-Infante et al. 2010).

The manufacture of many breakfast cereals starts with the cooking of whole cereal grains in a rotary pressure cooker. During this operation, the grains absorb heat and moisture, and undergo chemical (browning reactions) and physico-chemical changes as a consequence. The cooking stage is thought to have a key influence on the properties of the final product, such as colour, flavour and texture. Horrobin et al. (2003) studied the interior and surface colour development during wheat grain steaming and the results obtained indicated the possible relationship between the colour development and moisture uptake during the cooking process. In a study on the effects of oven humidity on foods (bread, cakes and cookies) baked in gas convection ovens, Xue et al. (2004) observed that increased oven humidity results in products with lighter colour and reduced firmness.

As aforementioned, the formation of MR products and intense colour are responsible for the organoleptic properties of this type of products. Moreover, it is also important to consider that the brown pigments formed could present some biological activities. Thus, Bressa et al. (1996) observed a considerable antioxidant capacity in cookies during the first 20–30 minutes of cooking (when browning takes place). Whole grain breakfast cereals have also proved to be an important dietary source of antioxidants (Miller et al. 2000). Borrelli et al. (2003) studied in bread and biscuits the formation of coloured compounds and they examined the antioxidant activity and the potential cytotoxic effects of the formed products. Summa et al. (2006) also correlated acrylamide concentration and antioxidant activity with colour of cookies by means of a three-dimensional model in which the three coordinates of the CIE colour space were used as variables.

Bernussi et al. (1998) studied the effect of microwave baking on the moisture gradient and overall quality of cookies, and they observed that colour did not differ significantly from that of the control samples (cookies baked using the traditional process).

Broyart et al. (1998) carried out a study on the kinetics of colour formation during the baking of crackers in a static electrically heated oven. These authors observed that the darkening step starts when the product temperature reaches a critical value in the range of 105–115°C. A kinetic model was developed in order to predict the lightness variation of the cracker surface using the product temperature and moisture content variations during baking. The evolution of lightness appears to follow a first-order kinetic influenced by these two parameters.

Colour development has also been included, together with other parameters (temperature, water loss, etc) in a mathematical model that simulated the functioning of a continuous industrial-scale biscuit oven (Broyart and Trystram 2003).

The effect of raising agents and sugars on surface colour of cookies was studied by Gökmen et al. (2008b).

Changes in surface colour, water activity and pH of cookies were determined to understand the chemical mechanisms responsible for HMF formation during baking of cookies from different formulations.

FLUORESCENCE

During the advanced stages of the non-enzymatic browning, compounds with fluorescence properties are also produced. Several analytical methods based on fluorescence measurements have been used to evaluate the extent of this reaction (Rizkallah et al. 2008, Trégoat et al. 2009, Calvarro et al. 2009). For instance, the FAST (fluorescence of advanced Maillard products and soluble tryptophan) method proposed by Birlouez-Aragon et al. (1998) is based on the fluorescence ratio between MR products and tryptophan determined when excited at 330–350 nm. This parameter is dependent on heat treatment of the product and is related to its protein nutritional loss. Thus, this method, firstly validated on milk samples, has been used in other foods modified by the MR such as breakfast cereals (Birlouez-Aragon et al. 2001) and rye bread (Michalska et al. 2008).

Birlouez-Aragon et al. (2001) studied the correlation between the FAST index, lysine loss and HMF formation during the manufacture of breakfast cereals by extrusion and in commercial samples. The FAST index was in good agreement with HMF formation. These authors also found that the relationship between FAST index and lysine loss indicates that, for severe treatments inducing lysine blockage higher than 30%, lysine loss is less rapid than the increase in the FAST index. Thus, the fluorimetric FAST method appears to be an interesting alternative to evaluate the nutritional damage on a great variety of cereal-based products submitted to heat treatment.

Delgado-Andrade et al. (2006) determined free and total (free + linked-to-protein backbone) fluorescence intermediate compounds (FIC) related to MR in commercial breakfast cereals. Levels of free and total FIC were also correlated with other well-established heat-induced markers of the extent of the MR or sugar caramelisation during cereal processing, such as HMF, furfural, GIM and furosine. Data support the usefulness of FIC measurements as an unspecific but adequate heat-induced marker of the extent of thermal processing in breakfast cereals, since statistically significant correlations were found between
Figure 30.2. Anomeric forms of maltulose.

FIC values and other heat-induced markers. Recently, Calvarro et al. (2009) reported a new methodology to monitor Maillard-derived fluorescent compounds (FC) in cookies by flow-injection analysis. Ratio between total and free FC was proposed as reference for setting the limits to the appropriate range of processing and to avoid over-processing. Because of the significant correlation with acrylamide levels, this methodology is also proposed for estimation of acrylamide formed in cookies.

ACRYLAMIDE

For almost 8 years now, a significant amount of research activities has focused on the mitigation of the formation of the 'probable carcinogen to human', acrylamide (2-propenamide), in a number of fried and oven-cooked foods (IARC 1994, Jensen et al. 2008). One of the possible mechanisms involved in the acrylamide formation is the reaction between asparagine and reducing sugars such as glucose or fructose via MR (Mottram et al. 2002, Weisshaar and Gutsche 2002, Courel et al. 2009). Since asparagine is a major amino acid in cereals, the possible formation of acrylamide in cereal-based foods should be considered.

Variable amounts of acrylamide have been found in cereal-based foods such as bread, cookies, crackers, biscuits and breakfast cereals (Yoshida et al. 2002, Ono et al. 2003, Riediker and Stadler 2003, Delatour et al. 2004, Taeymans et al. 2004, Rufián-Henares et al. 2006b, Sadd et al. 2008).

The presence of acrylamide, together with that of other undesirable Maillard compounds, such as furosine, HMF, carboxymethyllysine, has been related to formulation and processing conditions of model systems of cookies (Courel et al. 2009) and crackers (Levine and Smith 2005). In general, baking conditions, the selected leavening agent and addition of asparagine to the formula were identified as the most significant sources of variability (including those contributing either to the formation or elimination) of acrylamide. In a similar approach by Rufián-Henares et al. (2006b), the relationship among levels of acrylamide and compositional parameters (type of cereal and protein and dietary fibre contents) of commercial breakfast cereals was shown. In addition, no significant relationship between acrylamide and classical browning indicators such as HMF, furosine or coloured compounds was found in the commercial samples analysed. However, it could be feasible that this relation become significant for samples processed at industrial/

pilot-scale under controlled formulation and processing conditions.

Sadd et al. (2008) studied different alternative mitigation strategies to reduce acrylamide in bakery products. Whereas yeast fermentation was an effective way of reducing asparagine and hence acrylamide, amino acid addition to dough gave modest reduction of this contaminant. Removing ammonium-based raising agents was also beneficial. Calcium supplementation for binding asparagine looked promising, but interactions with other ingredients need further investigation. Lowering the dough pH reduced acrylamide, but at the expense of higher levels of other process contaminants.

Alternatively, Anese et al. (2010) have recently evaluated the possibility to remove acrylamide from previously hydrated commercial biscuits by vacuum treatment. Selection of suitable temperature, time and pressure conditions has proved to be required to maximise acrylamide removal while minimising its formation and effect on the sensory properties.

On the other hand, the correlation between mitigation of acrylamide and its influence on beneficial properties of food, such as the antioxidant activity has been scarcely studied. Summa et al. (2006) reported a strong link between the composition of the pastries and baking parameters and the genesis of acrylamide as well as antioxidants. Therefore, suppressing the MR generally leads not only to acrylamide mitigation but also to losses of substances considered to be beneficial.

MALTULOSE

Besides MR, isomerisation of reducing carbohydrates may take place during processing of cookies, crackers and breakfast cereals. Maltulose (Fig. 30.2), an epimerisation product of maltose, has been found in the crust of bread (Westerlund et al. 1989). Maltulose formation has also been observed during the heating of a maltodextrin solution at high temperature (180°C) (Kroh et al. 1996). García-Baños et al. (2000, 2002) detected maltulose in commercial enteral products and proposed the ratio maltose:maltulose as a heat treatment and storage indicator of enteral formulas.

In cookies, crackers and breakfast cereals, Rada-Mendoza et al. (2004) detected maltulose (from traces to 842 mg/100 g) in all commercial samples analysed. Figure 30.3 shows the gas chromatographic profile of the trimethylsilyl oxime-derivatives of mono- and disaccharide fractions of a cookie sample. Similar patterns were obtained for crackers and breakfast cereals. The formation of maltulose depends mainly on initial maltose
Figure 30.3. Gas chromatographic profile of the trimethylsilyl oxime-derivatives of fructose (1,2), glucose (3,4), sucrose (6), lactulose (8), lactose (9, 10), maltulose (11, 12) and maltose (13,14) of a cookie sample. Peaks 5 and 7 were the internal standards: *myo*-inositol and trehalose, respectively (from Rada-Mendoza et al. 2004).

content, pH and heat treatment intensity of the process. Since cookies, crackers and breakfast cereal samples may contain variable amounts of maltose, the usefulness of maltulose as indicator of heat treatment might be questionable. Previous studies on the formation of maltulose during heating of enteral formulas (García-Baños et al. 2002) pointed out that values of the ratio maltose:maltulose were similar in samples with different maltose content submitted to the same heat treatment. Therefore, the ratio maltose: maltulose is an adequate parameter for comparing samples with different initial maltose contents. Because maltose isomerisation increases with pH, only in samples with similar pH, differences in maltose: maltulose ratio can be due to different heat processing conditions. These results, shown by Rada-Mendoza et al. (2004), seem to indicate that the ratio maltose: maltulose can allow the differentiation among commercial cereal-based products and may serve as an indicator of the heat load during its manufacture.

Bakery and Cereal Products

J. A. Narvhus and T. Sørhaug

INTRODUCTION

Cereals are the edible seeds of plants of the grass family. They can be grown in a large part of the world and provide the staple food for most of mankind. Maize, wheat, and rice contribute about equally to 85% of world cereal production, which is at present about 2000 million tons (FAO 1999).

Cereals in their dry state are not subjected to fermentation due to their low water content. Properly dried cereals contain less than 14% water, and this limits microbial growth and chemical changes during storage. However, on mixing grains or cereal flour with water or other water-based fluids, enzymatic changes occur that may be attributed to the enzymes inherent in the grain itself and/or to microorganisms. These microorganisms can either be those present as the natural contaminating flora of the cereal, or they can be added as a starter culture.

This chapter will be mainly devoted to fermented bakery products made from wheat. However, on a global basis, many fermented cereal products are derived wholly or in part from other grains such as rice, maize, sorghum, millet, barley, and rye. Different cereals differ not only in nutrient content, but also in the composition of the protein and carbohydrate polymers. The functional and sensory characteristics of products made from different cereals will therefore vary at the outset due to these factors. In addition to this, the opportunity to vary technological procedures and microbiological content and activity provides us with the vast range of fermented cereal products that are prepared and consumed in the world today.

CEREAL COMPOSITION

Carbohydrates are quantitatively the most important constituents of cereal grains, contributing 77–87% of the total dry matter. In wheat, the carbohydrate in the endosperm is mainly starch, whereas the pericarp, testa, and aleurone contain most of the

crude and dietary fiber present in the grain. The pericarp, testa, and aleurone also contain over half of the total mineral matter. Whole meal flour is derived, by definition, from the whole grain and contains all its nutrients. When wheat is milled into flour, the yield of flour from the grain (extraction rate) reflects the extent to which the bran and the germ are removed and thereby determines not only the whiteness of the flour, but also its nutritive value and baking properties. Decreasing extraction rate results in a marked, and nutritionally important, decrease in fiber, fat, vitamins, and minerals (Kent 1983). The protein content of different cereal grains varies between 7% and 20%, governed not only by cereal genus, species, or variety (i.e., genetically regulated), but also by plant growth conditions such as temperature, availability of water during plant growth, and also of nitrogen and other minerals in the soil. There is an uneven distribution of different protein types in the different parts of the grain, so that although the protein concentration is not radically affected by milling, the proteins present in different milling fractions will vary.

STARCH

The starch in cereals is contained in granules that vary in size, from 2–3 μm to about 30 μm according to grain species. Barley, rye, and wheat have starch granules with a bimodal size distribution, with large lenticular and small spherical grains. Almost 100% of the starch granule is composed of the polysaccharides amylose and amylopectin, and the relative proportions of these polymers vary not only according to species of cereal, but also according to variety within a species. However, both wheat and maize contain about 28% amylose, but in wheat the ratio of amylose to amylopectin does not vary (Fenema 1996, Hoseney 1998). The amylose molecule is essentially linear, with up to 5000 glucose molecules polymerized by α-1,4 linkages and only occasional α-1,6 linkages. Amylopectin is a much larger (up to 10^6 glucose units) and more highly branched molecule with approximately 4% of α-1,6 linkages that cause branching in the α-1,4 glucosidic chain.

During milling of grains, some of the starch granules become damaged, particularly in hard wheat. The starch exposed in these broken granules is more susceptible to attack by amylases and also absorbs water much more readily. Therefore, the degree of damage to the starch grains dictates the functionality of the flour in various baking processes. When water is added to starch grains, they absorb water, and soluble starch leaks out of damaged granules. Heating of this mixture results in an increase in viscosity and a pasting of the starch, which on further heating leads to gelatinization as the ordered crystalline structure is disrupted and water forms hydration layers around the separated molecules. The gelatinization temperature of starch from different cereals varies from 55°C to 78°C, partly due to the ratio of amylose to amylopectin. The gelatinization of wheat starts at about 60°C. Despite the fact that there is not sufficient water to totally hydrate the starch in most bakery foods, the heat causes irreversible changes to the starch. On cooling a heated cereal product, some starch molecules reassociate, causing firming of the product.

Nonstarch polysaccharides, the pentosans, which are principally arabinoxylans, comprise approximately 2–3% of the weight of flour. They are derived from the grain cell walls and are polymers that may contain both pentoses and hexoses. They are able to absorb many times their own weight in water and contribute in baking by increasing the viscosity of the aqueous phase, but they may also compete with the gluten proteins for available water. Cereals also contain small amounts (1–3%) of mono-, di- and oligosaccharides, and these are important as an energy source for yeast at the start of dough fermentation.

PROTEIN

Cereal proteins contribute to the nutritional value of the diet, and therefore the composition and amount of protein present are inherently important. However, the protein content in cereals also has several important aspects in fermented bakery products. The amount and type of some of the proteins is important for the formation of an elastic dough and for its gas-retaining properties. Other proteins in cereals are enzymes with specific functions, not only for the developing germ, but also for various changes that take place from the processing of flour to bakery products.

Gluten Proteins

The unique storage proteins of wheat are also the functional proteins in baking. The gliadins and glutenins, collectively called gluten proteins, make up about 80% of the total protein in the grain and are mostly found in the endosperm. These proteins have very limited solubility in water or salt solutions, unlike albumins and globulins (Fig. 31.1). A good bread flour (known as "strong" flour) must contain adequate amounts of gluten proteins to give the desired dough characteristics, and extra gluten may be added to the bread formulation.

Enzyme Proteins

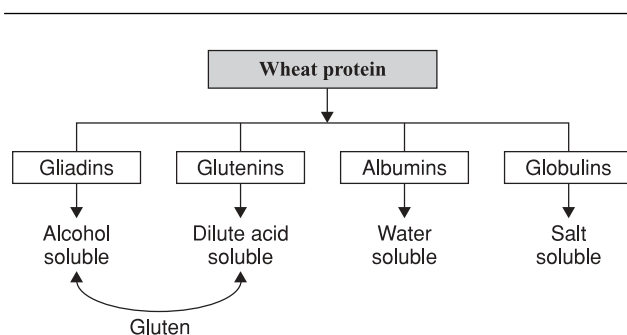
The albumin and globulin proteins are concentrated in the bran, germ, and aleurone.


Figure 31.1. Wheat proteins.

Amylases The primary function of starch-hydrolyzing enzymes is to mobilize the storage polysaccharides to readily metabolized carbohydrates when the grain germinates (Hoseney 1998).

α-Amylase hydrolyzes α-1,4 glycosidic bonds at random in the starch molecule chain but is unable to attack the α-1,6 linkages at the branching points on the amylopectin molecule. The activity of α-amylase causes a rapid reduction in size of the large starch molecule, and the viscosity of a heated solution or slurry of starch is greatly decreased. It is most active on gelatinized starch, but granular starch is also slowly degraded.

β-Amylase splits off two glucose units (maltose) at a time from the nonreducing end of the starch chain, thus providing a large amount of fermentable carbohydrate. β-Amylase is also called a saccharifying enzyme since its action causes a marked increase in sweetness of the hydrated cereal. Neither the hydrolysis of amylopectin nor of amylose is completed by β-amylase, since the enzyme is not able to move past the branching points. The presence of both α- and β-amylases, however, leads to a much more comprehensive hydrolysis, since α-amylase produces several new reducing ends in each starch molecule.

The level of α-amylase is very low in intact grain but increases markedly on germination, whereas β-amylase levels in intact and germinated grain are similar.

Flour containing too much α-amylase absorbs less water and therefore results in heavy bread. In addition, the dough is sticky and hard to handle, and the texture of the loaf is usually faulty, having large open holes and a sticky crumb texture. However, some activity is required, and bakers may add amylase either as an enzyme preparation or as wheat or barley malt in order to slightly increase loaf volume and improve crumb texture. The thermal stability of amylases from different sources dictates their activity during the baking process. Microbial amylases with greater thermal stability have been used in bread to decrease firming (retrogradation) upon storage since these enzymes are not fully denatured during baking.

Proteases Proteinases and peptidases are found in cereals, and their primary function is to make small amino nitrogen compounds available for the developing seed embryo during germination, when the levels of these enzymes also increase. However, whether these enzymes have a role in bread baking is not certain. Peptidases may furnish the yeast with soluble nitrogen during fermentation, and a proteinase in wheat that is active at low pH may be important in acidic fermentations such as sourdough bread.

Lipases Lipases are present in all grains, but oats and pearl millet have a relatively high activity of lipase compared with wheat or barley (Linko et al. 1997). In flour of the former grain types, hydrolytic rancidity of the grain lipids and added baking fat may be a problem.

LIPIDS

Lipids are present in grains as a large number of different compounds, and they vary from species to species and also within each cereal grain. Most lipids are found within the germ. Wheat flour contains about 2.5% lipids, of which about 1% are polar lipids (tri- and diglycerides, free fatty acids, and sterol esters) and 1.5% are nonpolar lipids (phospholipids and galactosyl glycerides). During dough mixing, much of the lipid forms hydrophobic bonds to the gluten protein (Hoseney 1998).

BREAD

Many different types of bread are produced in the world. Bread formulations and technologies differ both within and between countries due to both traditional and technological factors including: (1) which cereals are traditionally grown in a country and their suitability for bread baking, (2) the status of bread in the traditional diet, (3) changes in lifestyle and living standards, (4) globalization of eating habits, and (5) economic possibilities for investing in new types of bread-making equipment.

The basic production of most bread involves the addition of water to wheat flour, yeast, and salt. Other cereal flours may be blended into the mixture, and other optional ingredients include sugar, fat, malt flour, milk and milk products, emulsifiers, and gluten (for further ingredients and their roles in bread, see Table 31.1). The mixture is worked into an elastic dough that is then leavened by the yeast to a soft and spongy dough that retains its shape and porosity when baked. An exception to this is the production of bread containing 20–100% rye flour, where the application of sourdough and low pH are required.

BREAD FORMULATION

The formulation of bread is determined by several factors. In a simple bread, the baking properties of the flour are of vital importance in determining the characteristics of the loaf using a given technology. In addition, the bread obtained from using poor bread flour or suboptimum technology may be improved by using certain additives (Table 31.1).

The major methods used to prepare bread are summarized in Figure 31.2. In the straight dough method, all the ingredients are added together at the start of the process, which includes two fermentation steps and then two proofing steps. In the sponge and dough method, only part of the dry ingredients are added to the water, and this soft dough undergoes a fermentation of about 5 hours before the remainder of the ingredients are added and the dough is kneaded to develop the structure. Although these processes are time consuming, their advantages are that they develop a good flavor in the bread and that the timing and technology of the processes are less critical (Hoseney 1998). Mechanical dough development processes, such as the Chorleywood bread process developed in the United Kingdom in the 1960s, radically cut down the total bread-making time. The fermentation step is virtually eliminated, and dough formation is achieved by intense mechanical mixing and by various additives that hasten the process (Kent 1983). The resulting loaf has a high volume and a thin crust but lacks flavor and aroma. The trend is now away from this kind of process due to customer demand for more flavorful bread and reduced use of additives.

Table 31.1. Bread Additives

Dough Additive	Role
Cysteine. Sodium sulphite and metabisulphite[a]	Reducing agent. Aids optimal dough development during mixing by disrupting disulphide (–S–S–) bonds. A "dough relaxer."
Amylase	Releases soluble carbohydrate for yeast fermentation and Maillard browning reaction. Reduces starch retrogradation.
Ascorbic acid	Oxidizing agent. Strengthens gluten and increases bread volume by improving gas retention.
Potassium iodate, calcium iodate; calcium peroxide; azodicarbonamide[a]	Fast-acting oxidants; oxidizes flour lipids, carotene and converts sulphydryl (–SH) groups to disulphide (–S–S–) bonds.
Potassium and calcium bromates[a]	Delayed-acting oxidants: Develops dough consistency, reduces proofing stage.
Emulsifiers, strengtheners/conditioners and crumb softeners	Dispersion of fat in the dough. Increase dough extensibility. Interact with the gluten-starch complex and thereby retard staling.
Soy flour	Increases nutritional value, bleaches flour pigments, increases in loaf volume, increases crumb firmness and crust appearance, promotes a longer shelf life.
Vital wheat gluten and its derivatives	Increases gluten content, used especially when mixing time or fer- mentation time is reduced. Water adsorbant. Improves dough and loaf properties.
Hydrocolloids: Starch-based products from various plants	Regulates water distribution and water-holding capacity and thereby improves yield. Strengthens bread crumb structure and improves digestibility.
Cellulose and cellulose-based derivatives	Source of dietary fiber.
Salt	Enhances flavor (ca. 2% based on flour weight) and modifies mixing time for bread and rolls. Increases dough stability, firmness and gas retention properties. Raises starch gelatinization temperature

THE DEVELOPMENT OF DOUGH STRUCTURE

When wheat flour and water are mixed together in an approximately 3:1 ratio and kneaded, a viscoelastic dough is formed that can entrap the gas formed during the subsequent fermentation. The amount of water absorbed by the flour is dependent upon, and therefore must be adjusted to, the integrity of the starch granules and the amount of protein present. A high proportion of damaged granules, as found in hard wheat flour, results in greater water absorption. The unique elastic property of the dough is due to the nature of the gluten proteins. Hydrated gliadin is sticky and extensible, whereas glutenin is cohesive and plastic. When hydrated during the mixing process, the gluten proteins unfold and bond with each other by forming a complex (gluten) as kneading proceeds, with an increasing number of cross-linkages between the protein molecules as they become aligned. Disulphide bonds (-S-S-) break and re-form within and between the protein molecules during mixing.

Gluten does not form spontaneously when flour and water are mixed; energy must be provided (i.e., in the actual mixing process) in order for the molecular bonds to break and re-form as the gluten structure. At this point, the dough stiffens and becomes smooth and shiny. The gluten is now composed of protein sheets in which the starch granules are embedded. In addition, free polar lipids and glycolipids are incorporated in the complex by hydrophobic and hydrogen bonds. The properties of the dough are determined by the amount of protein present and by the relative proportions of the gluten proteins.

Another important part of the dough formation is the incorporation of air, in particular nitrogen. This forms insoluble bubbles in the dough that become weak points where carbon dioxide collects during the subsequent fermentation step. In the Chorleywood bread process, the dough is mixed under partial vacuum so that the incorporated bubbles expand and are then split into many small ones as mixing continues, thus giving a fine-pored loaf crumb after baking.

DOUGH FERMENTATION

During the fermentation step, several processes happen simultaneously, and in order to produce a bread of the required quality characteristics, each of these processes must be optimized to that end.

Yeasts have been used to leaven bread for thousands of years, but only in comparatively recent times have pure cultures of the yeast *Saccharomyces cerevisiae* been added to the bread dough as a leavening agent. The commercial production of baker's yeast follows procedures similar to those used in the production of brewing, wine making, and distilling strains of this same species. Indeed, the baking industry was originally supplied with yeast waste from the brewing industry until about 1860 (Ponte and Tsen 1987). However, commercial production of yeast biomass specifically for the baking industry developed alongside an increasingly expanding manufacture of bread in commercial bakeries and the development of the technology that provided the great volumes required by the industry.

Commercial Production of Baker's Yeast

S. cerevisiae was originally produced commercially using grain mash as a growth substrate, but for economic reasons, it is now grown on sucrose-rich molasses, a by-product from the sugar cane or sugar beet refining industry. Nitrogen, phosphorous, and essential mineral ions such as magnesium are added to promote growth. The production of the yeast biomass for the baking industry is multistage and takes about 10–13 hours at 30°C. *S. cerevisiae* shows the Crabtree effect, as its metabolism favors fermentative metabolism at high levels of energy-giving substrate, thus resulting in a low production of biomass (Walker 1998a). To avoid this, molasses is added incrementally toward the end of the production of yeast biomass, and the mixture is vigorously aerated in order to promote respiration and avoid fermentative metabolism. At the end of the production, the yeast is allowed to "ripen" by aeration in the absence of nutrients. This step synchronizes the yeast cells into the stationary growth phase and also promotes an increase in the storage sugar trehalose in the cells, thus improving their viability and activity.

When the fermentation is complete, the amount of yeast is about 3.5–4% w/v. The biomass is separated and concentrated by centrifugation and filtering. The yeast cream is then processed into pressed yeast or is dried. The most usual types of commercial yeast preparations are (Stear 1990) the following:

- *Cream yeast* is a near liquid form of baker's yeast that must be kept at refrigerated temperatures. It may be added directly to the bakery product being made.
- *Compressed yeast* is formed by filtering cream yeast under pressure to give approximately 30% solids. It has a refrigerated shelf life of 3 weeks.
- *Active dry yeast* (ADY) is produced by extruding compressed yeast through a perforated steel plate. The resulting thin strands are dried and then broken into short lengths to give a free-flowing granular product after further drying. Depending on the subsequent treatment and packaging, ADY may have a shelf life of over a year. However, ADY requires rehydration before application in dough, and this can be a labor-intensive operation in a large bakery. The product rehydrates best using steam or in water with added sugar at 40°C. Rehydration in pure water promotes leaching of cell contents and a reduction in the activity of the yeast.
- *High activity dry yeast* (HADY) (instant ADY, IADY) is a similar product, where improved drying techniques are used to give a product with smaller particle size that does not need to be rehydrated before use and can therefore be incorporated directly into bread dough without prior treatment.

Desirable Properties of Baker's Yeast

Yeast plays a critically important role in leavened bread production, and over the decades of commercial production, strains have been selected that give improved performance. Desirable characteristics include the following:

- High CO_2 production during the dough fermentation due to high glycolytic rate.

- The ability to quickly commence maltose utilization when the glucose in the flour is depleted.
- The ability to store high concentrations of trehalose, which gives tolerance to freezing and to high sugar and salt concentrations.
- Tolerance to bread preservatives such as propionate.
- Viability and retained activity during various storage conditions.

In the future, strains will probably be developed with even more useful properties. In particular, the flavor-forming properties will receive special attention (Walker 1998b).

The Role of Yeast in Leavened Bread

When yeast is incorporated into the dough, conditions allow a resumption of metabolic activity, although there is little actual multiplication of the yeast during shorter bread-making processes such as the straight dough and Chorleywood processes (Fig. 31.2). The yeast has been produced under aerobic (respiratory) conditions and is therefore adapted to this metabolism, but conditions very quickly become anaerobic in bread dough since the oxygen incorporated in the dough is soon depleted. The sugars are metabolized to pyruvate by glycolysis; pyruvate is then decarboxylated to acetaldehyde, thus producing carbon dioxide; and then ethanol is formed by reduction of acetaldehyde by $NADH_2$ (Fig. 31.3). For each molecule of glucose (or half molecule of maltose) that is metabolized, two molecules each of ethanol and carbon dioxide are produced. This fermentative metabolism is the prevalent pathway in *S. cerevisiae* in dough due both to the absence of oxygen and to the nonlimiting supply of fermentable sugars (Maloney and Foy 2003).

The amount of maltose available is a complex interaction between the amount of damaged starch, the level of amylases in the flour and the stage, and length of the fermentation process. Maltose accumulates during the early stages of the fermentation because it is generated by amylase but is not metabolized by the yeast because the presence of glucose represses maltose utilization.

When readily fermentable sugars (glucose and fructose) are exhausted, the yeast shows a lag in fermentation and then turns its metabolism to the maltose produced from the action of β-amylase on starch. If sucrose has been added in the bread formulation (e.g., 4%), this is fermented in preference to maltose, and the lag in the fermentation may not be observed. High amounts of added sucrose (e.g., 20%) significantly retard fermentation due to the high osmotic stress on the yeast (Maloney and Foy 2003).

The products of yeast metabolism in dough fermentation vary considerably with pH. In bread, the pH is usually below 6.0, but above this, end products in addition to ethanol and CO_2 are formed, such as succinate, acetic acid, and glycerol, and less ethanol and CO_2 are formed. *S. cerevisiae* is also able to degrade proteins and lipids, and several flavor compounds are produced (Fig. 31.3).

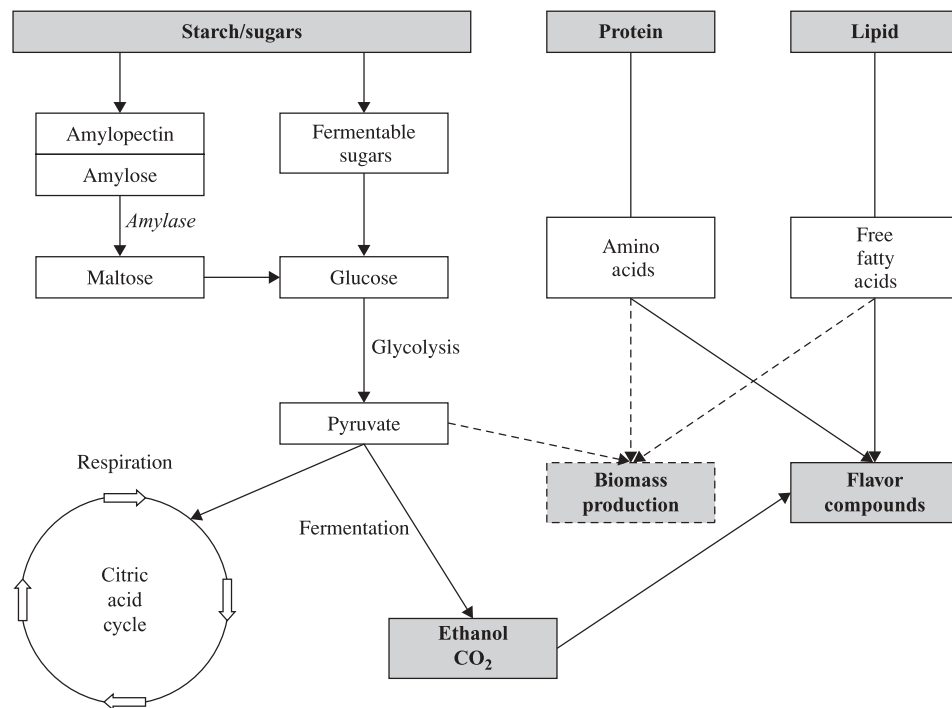
It is generally not considered that the yeast fermentation is important for bread flavor and aroma development in traditional


Figure 31.3. Biochemical changes during yeast fermentation of bread.

bread processes. However, the modern mechanical dough development processes, where the fermentation stage has been radically reduced, produce bread with a flavor that is inferior to that produced by the traditional straight dough process. This indicates that the yeast fermentation does make a positive contribution to bread flavor (Stear 1990). Zehentbauer and Grosch (1998) showed that yeast level and fermentation time and temperature affected aroma in the crust of baguettes, and they identified the flavor compounds 2-acetyl-1-pyrroline (roasty), methyl propanal and 2- and 3-methylbutanal (malty), and 1-octene-3-ol and (E)-2-nonenal (fatty). An increase in fermentation time allows for a development of flavor, but this trend is not really noticeable until much longer fermentation times are used, as in sourdough breads. There is not a clear borderline between regular bread and sourdough bread.

The production of ethanol and CO_2 is essential for the development of the desired bread crumb structure, and several factors affect both the development of the dough and its leavening (Fig. 31.4). During fermentation, some of the CO_2 is lost to the atmosphere, but most either collects in the small pockets of air incorporated during dough mixing or is dissolved in the dough's aqueous phase. The amount that can be dissolved in the aqueous phase is dependent on temperature, and is greater at lower temperatures. As the aqueous phase is already saturated with CO_2, it cannot escape from the bubbles by diffusion into the dough, so the bread begins to increase in volume. As the gas collects, the rheological properties of the dough allow it to expand in order to equalize the pressure that builds up. Ethanol reacts with the gluten to slightly soften it, allowing for easier expansion of the dough. It is important that CO_2 develop immediately after

dough preparation and proceed at an adequate intensity. In addition, the dough must have the physical properties necessary to withstand dough manipulation and allow for gas retention, so that the optimal structure has been obtained for the final proof and baking (Stear 1990).

THE BREAD-BAKING PROCESS

When the bread has undergone the final proofing and is put in the oven, the outer surface rapidly starts to form the crust. A temperature gradient develops due to transfer of heat from the pan to the loaf, and if the loaf is to achieve optimal properties, then the heat of the oven and the state of the bread proof need to be synchronized (Stear 1990). Apart from the outer crust, no part of the bread ever becomes dry; therefore, despite oven temperatures of well over 200°C, the temperature in most of the loaf will not exceed 100°C. The primary rise in temperature increases the activity of the yeast, and its production of CO_2. At the same time, the solubility of CO_2 decreases, ethanol and water evaporate, and the gases increase in volume. This results in a marked increase in the volume of the dough, called "oven spring."

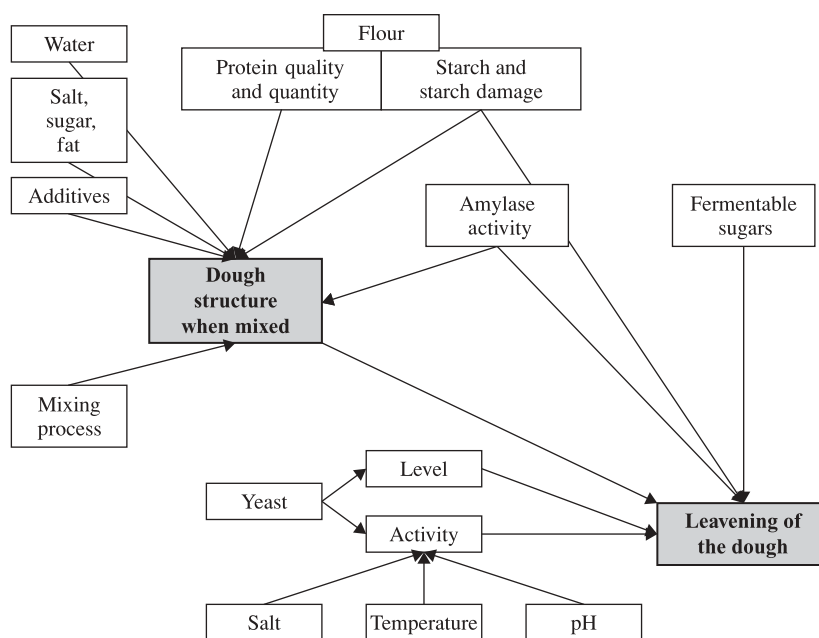
As the temperature in the loaf continues to rise, several other changes take place. The yeast is increasingly inhibited, and its enzymes are inactivated at about 65°C. The amylases in the dough are active until about 65–70°C is reached and a rapid increase in the amount of soluble carbohydrate takes place. Gelatinization of starch occurs at 55–65°C, and the water that this requires is taken from the gluten protein network, which then becomes more rigid, viscous, and elastic until a temperature is


Figure 31.4. Important factors for bread leavening.

reached at which the protein begins to coagulate. At this stage, the structure of the dough has changed to a more rigid structure due to denatured protein and gelatinized starch. These changes first occur near the crust and gradually move into the crumb as the heat is transferred inward.

Toward the end of baking, the temperature at the crust is much higher than 100°C. The crust becomes brown, and aroma compounds, predominantly aldehydes and ketones, are formed, mainly from Maillard reactions. The formation of flavor compounds is two staged. First, compounds are formed from the fermentation itself, and then during baking some of these compounds may react with each other or with the bread components to form other flavor compounds. Some other flavor compounds formed during the fermentation may be lost due to the high temperature, but those that remain gradually diffuse into the crumb after cooling. On further storage, the levels of flavor compounds decrease due to volatilization. Over 200 different flavor and aroma compounds have been identified in bread (Stear 1990).

Staling

The two main components of staling (firming of the bread crumb) are loss of moisture, mainly due to migration of moisture from the crumb to the crust (which becomes soft and leathery), and the retrogradation of starch. The major chemical change that occurs during staling is starch retrogradation, but a redistribution of water between the starch and the gluten also has been proposed. The gelatinization of the starch that occurs during cooking or baking gradually reverses, and the starch molecules form intermolecular bonds and crystallize, expelling water molecules and resulting in the firming of crumb texture. Starch retrogradation is a time- and temperature-dependent process and proceeds fastest at low temperatures, just above freezing point. Since the rearrangement of the starch molecules is facilitated by a high water activity, staling is retarded by the addition of ingredients that lower water activity (e.g., salt and sugar) or bind water (e.g., hydrocolloids and proteins). The staling rate can also be slowed by the incorporation of surfactants, shortening, or heat-stable α-amylase. Freezing of baked goods also retards staling since the water activity is drastically lowered. Much of the firming of the loaf during cooling is due to retrogradation of the amylose whereas the slower reaction of staling is due, in addition, to retrogradation of amylopectin (Hoseney 1998, Stear 1990).

SOURDOUGH BREAD

When cereal flour does not contain gluten, it is not suitable for production of leavened bread in the manner described above. However, if rye flour, which is very low in gluten proteins, is mixed with water and incubated at 25–30°C for a day or two, there is a good possibility that first step of sourdough production will be started. This mixture will regularly develop fermentation with lactic acid bacteria (LAB) and yeasts. This forms the basis of sourdough production, and this low-pH dough is able to leaven.

The use of cereal flour and water as a basis for spontaneous or directed fermentation products is common in many countries. In Africa, fermented porridge and gruel as well as their diluted thirst quenchers, are the main products of these natural fermentations, whereas Europeans and Americans and their descendants enjoy a variety of sourdough breads. In all these areas beers are also produced.

This great variety of fermented products has an historic prototype in the earliest reported leavened breads in Egypt about 1500 bc. Considering the simplicity of the process and the ease with which it succeeds, it has been suggested that peoples in several places must have shared this experience independently. It may be surmised that the experience with gruels and porridge preceded the idea of making bread.

Common bread fermented only with yeast appeared later in our history, and it was a staple food in the Roman Empire. This also indicates that the Romans had wheat with sufficient gluten potential.

It is possible to make leavened bread without gluten using sourdough, and this bread has become a favorite among many peoples (Hammes and Gänzle 1998, Wood 2000).

Advantages of Making Sourdough Bread

- Sourdough bread does not have to contain high levels of gluten for successful leavening.
- Low pH inhibits amylase, and thereby, degradation of starch is avoided.
- Sourdough improves the water-binding capacity of starch and the swelling and solubility of pentosans.
- Sourdough bread has very good keeping quality and an excellent safety potential.
- Less costly cereal flours can be used.
- A different variety of flavor and taste attributes can be offered.
- Sourdough bread can nutritionally compete with regular bread.
- Phytic acid is degraded by phytase in flour and from lactic acid bacteria. This improves the availability of iron and other minerals.
- Bread volume is increased, crumb quality is improved, and staling is delayed.

Rye flour is very low in gluten proteins, and instead, starch and pentosans make an important contribution to bread structure. The swelling and solubility of pentosans increase when LAB fermentation lowers pH. Gelatinization of starch occurs at about 55–58°C. Considering that the flour amylase has a temperature optimum around 50–52°C, it is crucial that the amylase is actually inactivated in the pH range that is obtained during sourdough fermentation. When mixtures of wheat and rye flour are used for bread making, a sourdough process is necessary if the content of rye flour exceeds 20%.

Rye and wheat flour contain phytic acid that binds minerals, particularly iron, that then become nutritionally unavailable. However, these cereals also contain phytases with pH optima around 5.0–5.5; thus, phytate degradation is very good in fermented flour, where these phytate complexes are also more soluble. Lactic acid bacteria also appear to have some phytase activity.

As wheat flour is able to form gluten, some of the considerations about amylases and starch are not equally relevant when baking wheat bread. Nevertheless, wheat flour is often used in sourdough bread.

However, preferred qualities like improved keeping and safety potential as well as the increased variety of flavors appeal to many consumers. These desirable qualities are also praised because they represent an alternative natural preservation method (Gobbetti 1998, Hammes and Gänzle 1998, Wood 2000).

MICROBIOLOGY OF SOURDOUGH

An established, "natural" sourdough is dominated by a few representatives of some bacteria and yeast species. This results from the selective ecological pressures exerted in the (rye) flour-water environment. Rye flour is an appropriate choice for this mixture because leavening of the dough is dependent on sourdough development. At the start of fermentation, a 50:50 (w/w) rye flour–water mixture at 25–30°C will harbor approximately the following:

Mesophilic micro-organisms, aerobes	10^3–10^7 cfu/g
Lactic acid bacteria	<10 to 5×10^2 cfu/g
Yeast	10–10^3 cfu/g
Molds	10^2 to 5×10^4 cfu/g

Among the mesophiles at the start, members of the Enterobacteriaceae dominate. Microorganisms dominating in the sourdough after 1–2 days at 25–30°C are as follows:

Lactic acid bacteria	10^9 cfu/g
Yeast	10^6 to 5×10^7 cfu/g

Some important properties of the rye flour–water environment determine that certain LAB and yeasts will compete most favorably. Lactobacilli have a superior ability to ferment maltose, they thrive despite limited iron due to the presence of phytic acid, and they are able to grow at about pH 5.0 and lower.

Reports show that different LAB may be isolated from sourdoughs; however, *Lactobacillus sanfrancis censis* has been found most often. Table 31.2 presents some of the other *Lactobacillus* species that have been isolated from sourdough. The selection of yeasts may be even narrower, with *Candida milleri* often cited (Table 31.2). Several other species are isolated occasionally (Spicher 1983, Gobbetti and Corsetti 1997, Hammes and Gänzle 1998, Martinez-Anaya 2003, Stolz 2003).

STARTERS

It is traditional bakers' practice to maintain a good sourdough over time by regular transfer, for example, every 8 hours. This is called "rebuilding." Such established cultures are referred to as Type I sourdoughs (Type I process), and a three-stage fermentation procedure is considered necessary to obtain an optimal sourdough. Each step is defined by specific dough yield, temperature, and incubation time.

Dough yield is defined as:

$$\frac{(Flour + Water) \, by \, weight}{Flour \, by \, weight} = \times 100 \, Dough \, yield$$

A high dough yield implies that a relatively large amount of water is used to make the dough; such a dough would conform with certain requirements in industrial production when there is a need to pump the dough.

The lactobacilli and yeasts in Table 31.2 are all common in sourdoughs; however, the composition of starter cultures for Type I processes have been continuously stably maintained for many years, and may be compared to certain mixed cultures in dairy technology. The LAB and yeasts in such cultures will be particularly well adjusted and adapted for the conditions in sourdoughs. In Germany, established natural sourdough starter cultures with a stable composition of *Lb. sanfranciscensis* and *Candida milleri* have been propagated for decades; they are marketed as "Reinzuchtsauerteig." When the sourdough process has been started through a one-stage or a three-stage procedure, a part of the optimized dough is withdrawn to start up the sourdough production for the next day. These sourdoughs are mentioned in different languages as Anstellgut (German), mother sponge (English), chef (French), masa madre (Spanish), madre (Italian).

Sourdoughs in Type II processes are used mainly for enhancing the flavor and taste of the regular bread. Addition of baker's yeast is required for efficient leavening. Type I sourdoughs are good alternatives as starters for the production of Type II sourdoughs. At the start of a production period, industrially large quantities of Type II sourdoughs may be stocked for portionwise use over time.

Sourdoughs for Type III processes are dried sourdough preparations.

Table 31.2. Common Representatives of Lactic Acid Bacteria and Yeasts Isolated from Mature Sourdoughs

	Heterofermentative	Homofermentative
Lactic acid bacteria	*Lactobacillus sanfranciscencis* (formerly *Lb.sanfrancisco, Lb. brevis* subsp. *lindneri*) *Lb. brevis, Lb. fructivorans, Lb. fermentum, Lb. pontis, Lb. sakei* (formerly *Lb. bavaricus, Lb. reuteri*)	*Lb. plantarum* *Lb. delbrueckii*
Yeasts	*Candida milleri, C. krusei, Saccharomyces cerevisiae, S. exiguus Torulopsis holmii, T. candida*	

Defined cultures have also been marketed; however, the suitability of Type I and Type II cultures appears to outcompete the alternatives offered. In addition to baker's yeast, the collection of defined cultures comprise at least pure cultures of *Lb. brevis* (heterofermentative) and *Lb. delbrueckii* and *Lb. plantarum* (homofermentative). The homofermentative cultures produce mainly lactic acid under anaerobic conditions, whereas the heterofermentative cultures will also produce acetic acid or ethanol and carbon dioxide. By controlling, if possible, the contributions from these different cultures, the relative amounts of acetic and lactic acids may be regulated. This important relationship:

$$\frac{\text{Lactic acid (Mole)}}{\text{Acetic acid (Mole)}}$$

is called the fermentation quotient (FQ).

Relatively mild acidity will have an FQ about 4–9, whereas a more strongly flavored rye bread, as produced in Germany, requires a much lower FQ, for example, 1.5–4.0 (Spicher 1983, Gobbetti and Corsetti 1997, Hammes and Gänzle 1998, Martinez-Anaya 2003, Stolz 2003).

SOURDOUGH PROCESSES

Several more or less traditional sourdough processes are practiced on a large scale in present-day bakery industry. (Fig. 31.5) One line comprises processes designed for baking with rye flour. They may be the Type I processes mentioned above. The Berliner short-sour process, the Detmolder one-stage process, and the Lönner one-stage process are typical for central and northern Europe. In every case, the process is initiated by a starter culture, 2–20% (often, 9–10%), in a rye flour–water (close to 50:50 w/w) mixture that is incubated for 3–24 hours at 20–35°C, depending on the process. When the resulting sourdough is ready, bread making starts with an "inoculation" of about 30% sourdough together with rye flour, wheat flour, baker's yeast, and salt. The final rye:wheat ratio is regularly 70:30 w/w. Dough yield is adjusted to satisfy handling (e.g., pumping) and microbial nutrition requirements.

Another line of sourdough processes comprises those for baking with wheat only. The San Francisco sourdough process is often mentioned in this connection; however, Italian wheat sourdough products, for example, Panettone, Colomba, and Pandoro, are also very important (Cauvain 1998, Gobbetti and Corsetti 1997, Spicher 1983, Wood 2000).

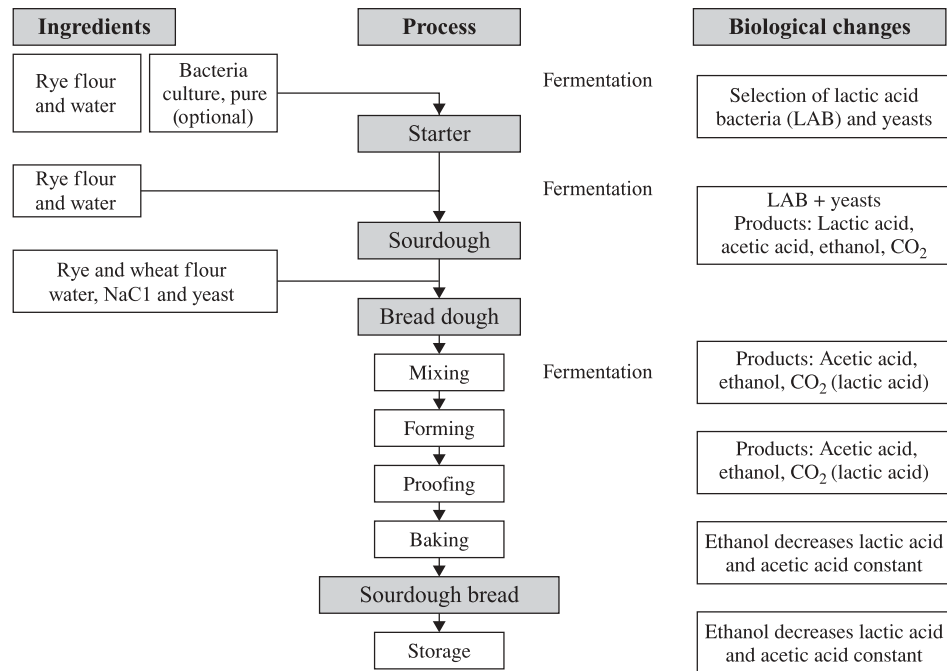
The starter for San Francisco sourdough is ideally rebuilt every 8 hours to maintain maximum activity. However, a mature sponge may be kept refrigerated for days with acceptable performance. For rebuilding the starter, sponge (40%) is mixed with high-gluten wheat flour (40%) and water (about 20%) to ferment at bakery temperature. Final bread making requires a dough consisting of the ripe sourdough (9.2%), regular wheat flour (45.7%), water (44.2%), and salt (0.9%). Proofing for 7 hours follows, during which the pH decreases from about 5.3 to about 3.9. A sourdough starter culture for San Francisco French bread production commonly contains *Lb. sanfranciscensis* and *Candida holmii*.


Figure 31.5. The sourdough process.

SELECTION AND BIOCHEMISTRY OF MICROORGANISMS IN SOURDOUGH

Sourdough breads based on rye or wheat flour or their mixtures enjoys a remarkable standing in many societies, either as established, traditional products or as "innovative" developments for more natural products and a wider choice of flavors. Well-functioning and popular sourdough starters that have been maintained by simple rebuilding for decades, and the reestablishment of the "same" stable starter over and over again from a constant quality flour, are both expressions of stable ecological conditions. The simplicity of the procedures may be somewhat deceiving with respect to the actual complexity of these biological systems. In the following sections, metabolic events and biochemical aspects of sourdough fermentation will be discussed. Attention will be drawn to some of the more clear points about the metabolic events and other biochemical facts. The near future should bring us closer to a comprehensive understanding.

Carbohydrate Metabolism

The development of a mixture (1:1) of rye flour or even wheat flour with water incubated some hours at 25–30°C will almost inevitably lead to a microbiological population consisting of lactic acid bacteria (LAB) and yeasts. It may need rebuilding several times in order to stabilize it, but from then on the composition of the microflora may be constant for years, provided the composition of the flour and the conditions for growth are not changed much. Representative LAB and yeasts have been presented in Table 31.2. These microorganisms have certain characteristics in common. First, the selected LAB are very efficient maltose fermenters, a prime reason why they competed so well in the first place. Several lactobacilli in sourdoughs, e.g. *Lb. sanfranciscensis, Lb. pontis, Lb. reuteri*, and *Lb. fermentum*, harbor a key enzyme, maltose phosphorylase, which cleaves maltose (the phosphorolytic reaction) to glucose-1-phosphate and glucose. Glucose-1-phosphate is metabolized heterofermentatively via the phosphogluconate pathway, while glucose is excreted into the growth medium. Glucose repression has not been observed with these lactobacilli. Most of the yeast species identified in sourdoughs are, per se, maltose negative, and will thus prefer to take up glucose when it is available. Other microorganisms may experience glucose repression of the maltose enzymes, to the benefit of the sourdough lactobacilli. Among the yeasts, *S. cerevisiae*, which is maltose positive and transports maltose and hexoses very efficiently, cannot take up maltose due to glucose repression and will, as a consequence, be defeated from the sourdough flora. *S. cerevisiae* as baker's yeast is, however, used at the bread-making stage, but as an addition in the recipe. Additional yeast cells may also be necessary for fast and efficient CO_2 production, because the yeasts are relatively sensitive to acids, particularly to acetic acid, which is excreted by the heterofermentative lactobacilli that often dominate the LAB flora of the sourdough. *Candida milleri* (syn. *S. exiguus, Torulopsis holmii*) is common in sourdoughs for San Francisco French bread. This yeast tolerates the acetic acid from heterolactic fermentation and thrives on glucose and sucrose in preference to maltose; it

thus appears to be a near ideal partner for *Lb. sanfranciscensis* (Gobbetti and Corsetti 1997, Gobbetti 1998, Wood 2000, Hammes and Gänzle 1998).

Wheat and rye flour contain mainly maltose as a readily available carbohydrate, although rye flour has greater amylase activity and therefore has a greater potential for release of maltose. Early work in the United States on *Lb. sanfranciscensis* indicated that this organism would only ferment maltose (Kline and Sugihara 1971). However, strains isolated in Europe appeared more diversified, and some of them would ferment up to eight different sugars (Hammes and Gänzle 1998). Utilization of maltose by *Lb. sanfranciscensis, Lb. pontis, Lb. reuteri*, and *Lb. fermentum* through phosphorolytic cleavage with maltose phosphorylase is energetically very favorable (Stolz et al. 1993) and shows increased cell yield and excretion of glucose when maltose is available. In these conditions the cells have very low levels of hexokinase.

Co-metabolism

Lactobacilli in sourdough production are not only specialized for maltose fermentation they also exploit co-fermentations for optimized energy yield (Gobbetti and Corsetti 1997, Hammes and Gänzle 1998, Stolz et al. 1995, Romano et al. 1987). *Lactobacillus sanfranciscensis, Lb. pontis* and *Lb. fermentum* all have mannitol dehydrogenase. Thus, fructose may be used as an electron acceptor for the reoxidation of NADH in maltose or glucose metabolism, and then acetylphosphate may react on acetate kinase to yield ATP and acetate (Axelsson 1993). The lactobacilli gain energetically and more acetic acid may contribute to the desirable taste and flavor of bread. In practical terms addition of fructose is used to increase acetate in the products, that is, lower FQ (Spicher 1983). Comparable regulation of acetate production may be achieved by providing citrate, malate or oxygen as electron acceptors, resulting in products like succinate, glycerol and acetate (Gobbetti and Corsetti 1996, Condon 1987, Stolz et al. 1993).

Proteolysis and Amino Compounds

In a sourdough, the flour contributes considerable amounts of amino acids and peptides; however, in order to satisfy nutritional requirements of growing LAB and provide sufficient amino compounds, precursors, for flavor development, some proteolytic action is necessary. The LAB have been suspected as the main contributors of proteinase and peptidase activities for release of amino acids in sourdoughs (Spicher and Nierle 1984, Spicher and Nierle 1988, Gobbetti et al. 1996), although the flour enzymes may also have considerable input (Hammes and Gänzle 1998). In addition, lysis of microbial cells, particularly yeast cells, add to the pool of amino acids; a stimulant peptide containing aspartic acid, cysteine, glutamic acid, glycine, and lysine that appears in the autolytic process of *C. milleri* has also been identified (Berg et al. 1981). *Lactobacillus sanfranciscensis* has been found to have a regime of intracellular peptidases, endopeptidase, and proteinase, as well as a dipeptidase and proteinase in the cell envelope (Gobbetti et al. 1996). Limited autolysis of

lactobacillus populations in sourdoughs may add to the repertoire of enzymes that will release amino acids from flour proteins, including those from proline-rich gluten in wheat. Some of the enzymes have been purified for further characterization (Gobbetti et al. 1996), and they express interesting activity levels at sourdough pH and temperatures.

The addition of exogenous microbial glucose oxidase, lipase, endoxylanase, α-amylase, or protease in the production of sourdough with 11 different LAB cultures showed positive effects on acidification rate and level for only three cultures, one *Leuconostoc citreum*, one *Lactococcus lactis* subsp. *lactis* and one *Lb. hilgardii*. *Lactobacillus hilgardii* with lipase, endoxylanase or α-amylase showed increased production of acetic acid. *Lactobacillus hilgardii* interacted with the different enzymes for higher stability and softening of doughs (Di Cagno et al. 2003).

Recent work with *Lb. sanfranciscensis, Lb. brevis*, and *Lb. alimentarius* in model sourdough fermentations showed, by using two-dimensional electrophoresis, that 37–42 polypeptides had been hydrolyzed. The polypeptides varied over wide ranges of pIs and molecular masses, and they originated from albumin, globulin, and gliadin, but not from glutenin. Free amino acid concentrations increased, in particular those of proline and glutamic and aspartic acid. Proteolysis by the lactobacilli had a positive effect on the softening of the dough. A toxic peptide for celiac patients, A-gliadin fragment 31–43, was degraded by enzymes from lactobacilli. The agglutination of human myelogenous leukemia–derived cells (K562) by toxic peptic-tryptic digest of gliadins was abolished by enzymes from lactobacilli (Di Cagno et al. 2002).

Volatile Compounds and Carbon Dioxide

Both yeasts and LAB contribute to CO_2 production in sourdough products, but the importance of the two varies. In bread production with only the (natural) sourdough microflora, the input from LAB may even be decisive for leavening because the counts and kinds of yeast may not be optimal for gas production. Relatively low temperature (e.g., 25°C) and low dough yield (e.g., 135) would select for LAB activities and less yeast metabolism. More complete volatile profiles were obtained at higher temperatures (e.g., 30°C) and with a more fluid dough. Of course, increasing the leavening time may give substantially richer volatile profiles (Gobbetti et al. 1995). If baker's yeast, *S. cerevisiae*, is added to optimize and speed up the production process, the contribution from yeasts will dominate (Gobbetti 1998, Hammes and Gänzle 1998).

Bread made with chemical acidification without fermentation starter failed in sensory analysis. This indicates that fermentation with yeasts and LAB is important for good flavor, although high quality raw materials and proofing and baking are also decisive factors. Flavor compounds distinguishing the different metabolic contributions in sourdough are as follows (Gobbetti 1998):

- *Yeast fermentation (alcoholic)*: 2-methyl-1-propanol, 2,3-methyl-1-butanol.
- *LAB homofermentative*: diacetyl, other carbonyls.
- *LAB heterofermentative*: ethyl acetate, other alcohols and carbonyls.

Antimicrobial Compounds from Sourdough LAB

The primary antimicrobial compounds produced by sourdough LAB are lactic and acetic acid, diacetyl, hydrogen peroxide, carbon dioxide, and ethanol, and among these, the two organic acids continue to be the most important contributions for beneficial effects in fermentations.

Researchers in the field, of course, also consider and test possibilities that LAB may produce bacteriocins and other antimicrobials. Thus antifungal compounds from *Lb. plantarum* 21B have been identified, for example, phenyl lactic acid and 4-hydroxyphenyl lactic acid (Lavermicocca et al. 2000). Caproic acid from *Lb. sanfranciscensis* also has some antifungal activity (Corsetti et al. 1998).

A real broad-spectrum antimicrobial from *Lb. reuteri* is reuterin (β-hydroxypropionic aldehyde), which comes as a monomer and a cyclic dimer (El-Ziney et al. 2000). Reutericyclin, which was isolated from *Lb. reuteri* LTH2584 after the screening of 65 lactobacilli, is a tetramic acid derivative. Reutericyclin inhibited Gram-positive bacteria (e.g., *Lactobacillus* spp., *Bacillus subtilis, B. cereus, Enterococcus faecalis, Staphylococcus aureus*, and *Listeria innocua*), and it was bactericidal towards *B. subtilis, S. aureus*, and *Lb. sanfranciscensis*. The ability to produce reutericyclin was stable in sourdough fermentations over a period of several years. Reutericyclin produced in sourdough was also active in the dough (Gänzle et al. 2000; Höltzel et al. 2000; Gänzle and Vogel 2003).

A few bacteriocins or bacteriocin-like compounds have also been identified, isolated, and characterized (Messens and De Vuyst 2002). Bavaricin A from *Lb. sakei* MI401 was selected by screening 335 LAB strains, including 58 positive strains (Larsen et al. 1993). Bavaricin A (and Bavaricin MN from *Lb. sakei* MN) have the *N*-terminal consensus motif of bacteriocin class IIA in common, comprise 41 and 42 amino acids, respectively, and have interesting sequence homologies and similar hydrophobic regions. Bavaricin A inhibits *Listeria* strains and some other Gram-positive bacteria but not *Bacillus* or *Staphylococcus* (Larsen et al. 1993, Kaiser and Montville 1996). Plantaricin ST31 is produced by *Lb. plantarum* ST; it contains 20 amino acids, and the activity spectrum includes several Gram-positive bacteria but not *Listeria* (Todorov et al. 1999). A bacteriocin-like compound, BLIS C57 from Lb. *sanfranciscensis* C57, was detected after screening 232 *Lactobacillus* isolates, including 52 strains expressing antimicrobial activity. BLIS C57 inhibits Gram-positive bacteria including bacilli and *Listeria* strains (Corsetti et al. 1996).

TRADITIONAL FERMENTED CEREAL PRODUCTS

Only two cereals, wheat and rye, contain gluten and are thereby suitable for the production of leavened bread, but many other food cereals are grown in the world. On a global basis, a great proportion of cereals are consumed as spontaneously fermented products, in particular in Africa, Asia, and Latin America. Most fermented cereals are dominated by lactic acid bacteria (LAB), and the microflora associated with the grains, flour, or any other ingredient, together with contamination from water,

food-making equipment, and the producers themselves, represent the initial fermentation flora. Malted flour is also an important source of microorganisms. The changes that take place during the fermentation are due to both the metabolism of the microorganisms present and the activity of enzymes in the cereal, and these are in turn affected by the great variety of technologies that are used. The technology may be simple, involving little more than a mixing of flour with water and allowing it to ferment, or it may be extremely complex and involve many steps with obscure roles. Indigenous fermented foods are usually based upon raw materials that have a sustainable production in their country of origin and are therefore attracting increasing interest from researchers—both within pure and applied food science and also in anthropology. These ancient technologies often have deep roots in the culture of a country, and there is increasing awareness of the importance of preserving these traditional foods. Many products are not yet described in the literature, and knowledge of them is in danger of disappearing. It is therefore necessary to document the technologies used and to identify the fermenting organisms and the metabolic changes that are essential for the characteristics of the product. It is, however, often difficult to describe the sensory attributes of a product that is inherently variable.

In Africa, as much as 77% of the total caloric consumption is provided by cereals, of which rice, maize, sorghum, and millet are most important. Cereals are also significant sources of protein. Most of the cereal foods consumed in Africa are traditional fermented products and are very important both as weaning foods and as staple foods and beverages for adults. In Asia, many products are based on rice, and maize is most widely utilized in Latin America (FAO 1999).

Indigenous fermented cereals can be classified according to raw material, type of fermentation, technology used, product usage, or geographical location. They can range from quite solid products such as baked flat breads to sour, sometimes mildly alcoholic, refreshing beverages.

Many factors have an influence on the characteristics of an indigenous product (Fig. 31.6). The choice of raw material may be primarily influenced by price and availability rather than by preference.

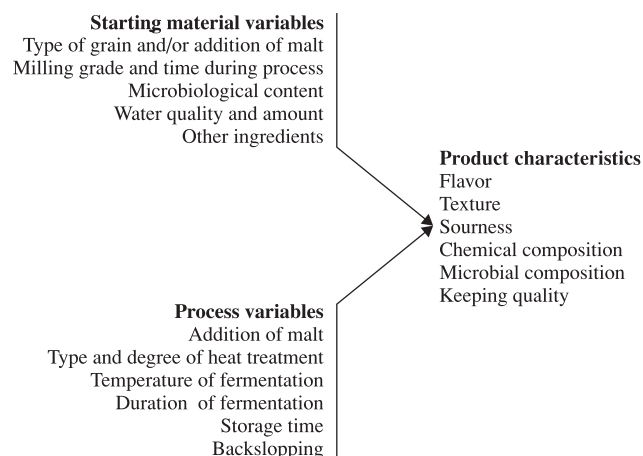
For instance Togwa, a Tanzanian fermented beverage, may be made from maize in the inland areas of Morogoro and Iringa, but from sorghum in the coastal areas of Dar es Salaam and Zanzibar (Mugula 2001). Similarly, the Ethiopian product borde may be made from several different grains according to availability—sorghum, maize, millet, barley and also the Ethiopian cereal tef (Abegaz et al. 2002). The use of different grains obviously affects the sensory characteristics of a product, and yet it may have the same name throughout the country. Some fermented cereal products also contain other ingredients. Idli is a leavened steamed cake made primarily from rice to which black gram dahl is added. This not only improves the nutritional quality, but in addition, the black gram imparts a viscosity, apparently specific for this legume, which may aid air entrapment during fermentation and thereby lighten the texture of the product (Soni and Sandu 1990). However, on a broader basis, the addition of legumes such as soybean flour to fermented cereals


Figure 31.6. Important factors determining the characteristics of spontaneously fermented cereal products.

has been suggested as an economically feasible way to generally improve the nutritional quality of cereal foods.

Some fermented cereal products are made using unmalted grain, with no extra addition of amylase, but they tend to either be very thick or of low nutritional density. Malted flour is added to many indigenous fermented cereals, a traditional technology that has far-reaching effects on several product characteristics. The addition of malt provides amylases (in particular, α-amylase) that hydrolyze the starch, sweeten the product, and also cause a considerable decrease in viscosity of the product after heat treatment. The malting process, the germination of grain following steeping in water, is associated with colossal microbiological proliferation, and the organisms that develop during malting are a source of fermenting organisms. Many Asian products, for example koji, a Japanese fermented cereal or soybean product, are first inoculated with a fungus, as a source of amylase, in order to liberate fermentable sugars from the cereal starch (Lotong 1998).

Many fermented cereals are multipurpose. A single product may be prepared in varying thicknesses and used as a fermented gruel for both adults and children, or it may be watered down and used as a fermented thirst-quenching beverage. As Wood (1994) remarked, the latter type of product makes a meaningful contribution to nutrition; the potential of their replacement by cola-type beverages would result in a serious negative impact on the nutrition of people in developing countries.

The use of fermented cereals as weaning foods in developing countries raises several important issues. Unfermented gruels deteriorate very rapidly in unhygienic conditions, especially if refrigeration is not available. They then represent a significant source of foodborne infections that annually claim the lives of millions of young children (Adams 1998). Fermented malted cereal gruels have been shown on the whole to contain low numbers of pathogenic organisms since these are inhibited and killed by the low pH that rapidly develops in the product.

Fermented cereals are therefore usually regarded as safer than their unfermented counterparts (Nout and Motarjemi 1997). A weaning food made from unmalted cereals may be a cause of malnutrition because its thick viscosity limits the nutritional intake of a small child. Addition of malted flour decreases the viscosity so that more food can be ingested. If the fermentation flora includes yeasts in addition to LAB, a measurable reduction of carbohydrate will occur due to the production of CO_2 and other volatile compounds (Muyanja 2001). Analysis of fermented cereal products therefore shows that the protein:carbohydrate ratio is improved during the fermentation, and this obviously has nutritional benefits.

Milling of cereals into flour is usually done prior to fermentation, but in some products, for example, borde (Ethiopia), wet milling is used. This technique can be used when mechanical grain mills are not available and if the product is required to be smooth and without bits of suspended bran. The starch is also liberated from the grain more thoroughly when slurried with water and sieved than if it has been previously dry milled (Abegaz 2002).

A heat treatment step is found at some point in the production technology of most fermented cereal products and may involve boiling, steaming, or roasting. The type of heating employed is likely to have an effect on the flavor of the product, certainly if the temperature attained is sufficient to promote Maillard reactions. The heat also gelatinizes the starch, making it more susceptible to amylolytic enzymes, thus providing greater amounts of fermentable carbohydrates. However, at the same time, most of the natural contaminating (and potentially fermenting) flora and cereal enzymes are destroyed. Such products are also prone to contamination after the heat treatment step, and are thereby potentially unsafe should pathogenic organisms grow during the subsequent fermentation. The traditional solution to this is to use "backslopping," the addition of some of a previous batch of the product, and/or the addition of malted flour. Regular backslopping results in a selection of acid-tolerant organisms and functions as an empirical starter culture.

Fermentation usually takes place at ambient temperatures, and this may cause seasonal variations in products due to selection of different microorganisms at different temperatures. The duration of fermentation is largely a matter of personal choice, based on expected sensory attributes. Heat treatment after fermentation makes for a safer product, but it has the disadvantage of change of taste or loss of volatile flavor and aroma compounds.

THE MICROFLORA OF SPONTANEOUSLY FERMENTED CEREALS

Spontaneously acid-fermented cereal products may contain a variety of microorganisms, but the flora in the final product is generally dominated by acid-tolerant LAB. Yeasts are also invariably present in large numbers when the fermentation is prolonged. A typical fermented cereal product contains approximately 10^9 and 10^7 cfu/g of product, of LAB and yeasts, respectively. However, since yeast cells are considerably larger than bacteria cells, their metabolic contribution to product characteristics is likely to be just as important as that of the LAB.

The buffer capacity of cereal slurries is low, and the pH therefore drops quickly as acid is produced. Pathogenic organisms are inhibited by a fast acid production, so the addition of starter cultures, either as a pure culture or by "backslopping" promotes acid production and contributes to the safety of the fermented product (Nout et al. 1989).

The potential and the need for upgrading traditional fermentation technologies have initiated considerable research (Holzapfel 2002). In some recent studies of spontaneously fermented cereals, the LAB and yeasts have been isolated and identified as a first stage towards developing starter cultures for small-scale production of traditional fermented cereals. Muyanja et al. (2003) recorded that bushera, a traditional Ugandan fermented sorghum beverage that contains high numbers of LAB, was usually consumed by children after one day of fermentation as "sweet bushera." After 2–4 days, the product became sour and alcoholic and was consumed by adults. However, the sweet bushera showed very high counts of coliforms and had a reputation for causing diarrhea (Muyanja 2001). Clearly, the development of defined starter cultures would improve the safety of this and similar products.

Some recent examples of studies on the microbial flora of spontaneously fermented cereals are shown in Table 31.3. For each product, several different types of organisms have been isolated. In other words, a specific product is not produced from fermentation by a specific organism or organisms. *Lb. plantarum* seems to be the most commonly isolated *Lactobacillus* species in fermented cereals. In addition, heterofermentative LAB such as leuconostocs, *Lb. brevis*, and *Lb. fermentum* frequently occur. Yeasts are always present in spontaneously fermented products, but few studies have characterized the predominating species. However, Jespersen (2003) reported that *S. cerevisiae* is the predominant yeast in many African fermented foods and beverages.

All spontaneously fermented products contain, or have contained, many different types of microorganisms. These have grown in the product and will have metabolized some of the cereal components, thereby making a contribution (positive or negative) with their metabolites to the overall sensory characteristics of that product. However, studies on spontaneously fermented products have focused on LAB and yeasts since these organisms are often associated with other, better known, fermented products and have a history of safe use in food. Stanton (1998) proposed that the nature of the substrate (raw material) and the technology used to produce fermented foods are the predominating factors that determine the development of microorganisms and, thereby, the properties of a product.

DESIRABLE PROPERTIES OF THE FERMENTING MICROFLORA

The most important property of a starter culture for a fermented cereal is the ability to quickly produce copious amounts of lactic acid in order to achieve a rapid decline in pH and retard the growth of pathogens and other undesirable organisms. Some workers (Sanni et al. 2002) have sought amylolytic LAB strains, as this could remove the need for using the highly contaminated

Table 31.3. Lactic Acid Bacteria and Yeasts Isolated from Some Traditional Fermented Cereal Products

Product (Country of Origin)	Cereal Basis	Most Prevalent		Reference
		Species of LAB	Species of Yeast	
Togwa (Tanzania)	Various	*Lb. brevis, Lb. cellobiosus, Lb. Plantarum* *W. confusa* *P. pentosaceus*	*P. orientalis* *S. cerevisiae* *C. pelliculosa* *C. tropicalis*	Mugula et al. 2003
Bushera (Uganda)	Sorghum, millet	*Lb. brevis; E. faecium* *Ln. mesenteroides* subsp. *mesenteroides*	NR	Muyanja et al. 2003
Ogi (Nigeria)	Maize	*Lb. reuteri, Lb. Leichmanii, Lb. plantarum, Lb. casei, Lb. fermentum,* *Lb. brevis, Lb. alimentarius, Lb. buchneri, Lb. jensenii.*	*S. ceveviseae and Candida mycoderma*	Ogunbanwo et al. 2003 Odunfa 1985
Pozol (Mexico)	Maize	*Streptococcus* spp., *Lb. plantarum, Lb. fermentum* *Lb. brevis* *Ln. mesenteroides* *Lc. lactis, Lc. raffinolactis*	*C. mycoderma, S. cerevisiae, Rhodotorula* spp.	Omar and Ampe 2000 Nuraida and others 1995
Borde (Ethiopia)	Various	*Lb. brevis* *W. confusa* *P. pentosaceus*	NR	Abegaz 2002
Idli (India)	Rice and blackgram beans	*Leuconostocs spp.* *Enterococcus faecalis*	*Saccharomyces* spp.	Soni and Sandu 1990

Note: Lb., Lactobacillus; Ln., Leuconostoc; L., Lactococcus; P., Pediococcus, E., Enterococcus; W., Weisella; S., Saccharomyces; I., Isa; NR, Not recorded.

malted flour in a product. The starter should also be able to hydrolyze the cereal protein in order to obtain the amino acids sufficient for rapid growth, and it should produce desirable and product-typical aroma and flavor compounds, but not off-flavors. Some products are characterized by a foaming consistency, and heterofermentative organisms (LAB or yeasts) are required for this property. Bacteriocin-producing strains have also been sought (Holzapfel 2002) in an attempt to increase the microbiological safety of the products. Starter cultures must also be commercially propagable and be able to survive preservation methods without loss of viability, activity, or metabolic traits.

MICROBIOLOGICAL AND BIOCHEMICAL CHANGES IN TRADITIONAL FERMENTED CEREALS

Few studies have been made on the biochemical changes that take place in traditional fermented cereals. Mugula et al. (2003) analyzed samples of naturally fermented togwa made from sorghum and maize, to which togwa was backslopped and malt was added. The development of groups of microorganisms, organic acids, soluble carbohydrates, and volatile components was studied during the 24-hour fermentation. Maltose and glucose increased during the first part of the fermentation due to the action of cereal amylases, but later were reduced as the growth of LAB and yeasts increased. The pH dropped from around 5.0 to 3.2 in 24 hours, and this was mirrored by a rise in lactic acid to about 0.5%. Ethanol and secondary alcohols and aldehydes increased during the secondary part of the fermentation. Malty flavors are typical for fermented cereal products and may be produced during grain malting. Secondary aldehydes and alcohols are responsible for these flavors and may also originate from microbial metabolism of the branched-chain amino acids leucine, isoleucine, and valine. These compounds are produced by yeasts, some LAB, and probably also by other microorganisms in the product.

Many spontaneously fermented cereals also have a very short shelf life, since fermentation continues in the absence of refrigeration. Off-flavors, in particular vinegary notes, are a common problem. The very low pH in fermented cereal products may be sensorially compensated for by saccharification by β-amylase.

FERMENTED PROBIOTIC CEREAL FOODS

A probiotic food is a live bacterial food supplement, which when ingested, may improve the well-being of the host in a variety of

ways by influencing the balance of the host's intestinal flora (Fuller 1989). Most probiotic bacteria have been isolated from the healthy human intestine and are members of the genus *Lactobacillus*, but some products may contain *Bifidobacterium* spp. or the yeast *Saccharomyces boulardii*. While the potential benefits of probiotic bacteria have been generally accepted for many decades, it is only in comparatively recent years that research has been able to scientifically document the beneficial medical effect due to some specific strains (Gorbach 2002). There is now strong scientific evidence that specific strains of probiotic microorganisms are able to:

- show a prophylactic action against and alleviate diarrhea caused by bacterial and viral infections, radiation therapy or the use of antibiotics;
- suppress undesirable bacteria in the gut with beneficial results for patients with conditions such as irritable bowel syndrome and ulcerative colitis;
- influence the immune system, showing positive results for infant atopic eczema and other allergies.

Indeed, in addition to the list above, other effects have been proposed: the lowering of blood cholesterol; the prevention of acute respiratory infections, *Helicobacter pylori* infections, and colonization by potential pathogens in intensive care units in hospitals; relief of constipation; and a protection against the development of various forms of cancer. However, so far, convincing proof for the efficacy of probiotics against these problems has not been obtained. The positive effects that have been documented have led to a great interest from food manufacturers and consumers alike. The main motivation for consuming probiotic products is said to be the developing consumer trend towards healthy living though natural foods and medicines and a trend away from the use of antibiotics and the incorporation of chemical additives in food. As the beneficial effects of probiotic foods become scientifically accepted, there will be increasing pressure from food manufacturers on the authorities to allow health claims to be used in product advertising. Probiotic fermented milks were the first probiotic products to be produced

commercially and are available in many countries (Tamime and Marshall 1997).

Some fermented probiotic cereal products are now being prepared and marketed (Table 31.4) and may have an appeal for those who do not consume dairy products.

Oats are a popular basis for probiotic cereal foods. This choice is due to the healthy image of oats with respect to soluble and insoluble fiber content and the potential to reduce blood cholesterol due to β-glucans. A prebiotic is a compound, usually an oligosaccharide, that reaches the colon undigested by the host's enzymes and selectively favors the growth of probiotic bacteria. Such compounds include lactulose, fructooligosaccharides, and inulin. It has been suggested that the best probiotic results may be obtained by using a combination of a prebiotic (such as oats) and a probiotic organism (Charalampopoulos et al. 2002). In this way, the total physiological effect of the food could be increased.

In order for a probiotic product to have a physiological effect, it has been suggested that it should contain at least 10^6 cfu/g product, and that daily intake should be at least 100 g (Sanders and Huis in't Veld 1999). The final acidity in the product has been shown to be of critical importance for the survival of probiotic bacteria during storage (Mårtensson, Öste and Holst 2002). Many probiotic bacteria do not tolerate a pH below 4.0, and fermented cereals frequently reach this pH due to the poor buffering capacity of the substrate. In addition, the physiological state of the probiotic organisms at the time of storage also determines their survival. Organisms that show poor growth during a fermentation period are more likely to die out during cold storage. This necessitates careful formulation of the product as well as selection of the right probiotic culture.

The choice of a substrate for a probiotic food is partially governed by the tolerance of the food towards heat pasteurization or even sterilization before fermentation, and cereal mixtures lend themselves well to this treatment. Probiotic products require fermentation at around 37°C for 8–18 hours, depending on substrate. The suitability of such conditions for the growth of pathogenic organisms necessitates strict adherence to hygiene both before and during fermentation. A fast lactic acid

Table 31.4. Fermented Probiotic Cereal Foods

Type of Product (Commercial Name)	Cereal Constituent	Probiotic Constituent	Reference
Fermented fruit flavored cereal drink (Pro Viva)	Oat + malted barley flour	*Lb. plantarum* 299v	Molin 2001
Fermented cereal drink	Oat "milk"	*LB. reuteri; lb. acidophilus; B. bifidus*	Mårtensson, Öste and Holst 2002
Fruit flavored cereal pudding (Yosa)	Oat flour	*Lb. acidophilus; B. bifidus*	Blandino et al. 2003
Cereal-based weaning food	Maize + malted barley flour	*Lb. acidophilus* *Lb. rhamnosus 'GG'* *Lb. reuteri*	Helland et al. 2004

Note: LB = Lactobacillus; B = Bifidobacterium.

development in the product during fermentation is a critical step, and the growth of probiotic organisms in cereal products is greatly stimulated by the addition of malted flour (either of the same grain or of barley malt) or milk, due to the increased availability of fermentable sugars, peptides, and amino acids. For probiotic weaning foods, the use of malt has a further advantage since at a given viscosity, the product has a higher nutritional den-sity.

Probiotic cereal foods are in their infancy, and the future will probably see further development in this type of product. New strains with proven probiotic efficacy and good flavor-forming abilities will increase the range of probiotic products available.

Starch Synthesis in the Potato Tuber

P. Geigenberger and A.R. Fernie

INTRODUCTION

Starch is the most important carbohydrate used for food and feed purposes and represents the major resource of our diet. The total yield of starch in rice, corn, wheat, and potato exceeds 10^9 tons/year (Kossmann and Lloyd 2000, Slattery et al. 2000). In addition to its use in a nonprocessed form, due to the low cost incurred, extracted starch is processed in many different ways. Processed starch is subsequently used in multiple forms, for example in high-fructose syrup, as a food additive, or for various technical processes based on the fact that as a soluble macromolecule it exhibits high viscosity and adhesive properties (Table 32.1). The considerable importance of starch has made increasing the content and engineering the structural properties of plant starches major goals of both classical breeding and biotechnology over the last few decades (Smith et al. 1997, Sonnewald et al. 1997, Regierer et al. 2002). Indeed, since the advent and widespread adoption of transgenic approaches some 15 years ago gave rise to the discipline of molecular plant physiology, much information has been obtained concerning the potential to manipulate plant metabolism. For this chapter, we intend to review genetic manipulation of starch metabolism in potato (*Solanum tuberosum*). Potato is one of the most important crops worldwide, ranking fourth in annual production behind the cereal species rice (*Oryza sativa*), wheat (*Triticum aestivum*), and maize (*Zea mais*). Although in Europe and North America the consumption of potatoes is mainly in the form of processed

foodstuffs such as fried potatoes and chips, in less developed countries it represents an important staple food and is grown by many subsistence farmers. The main reasons for the increasing popularity of the potato in developing countries are the high nutritional value of the tubers combined with the simplicity of its propagation by vegetative amplification (Fernie and Willmitzer 2001). Since all potato varieties are true tetraploids and display a high degree of heterozygosity, genetics have played only a minor role in metabolic studies in this species. However, because the potato is a member of the *Solanaceae* family, it was amongst the first crop plants to be accessible to transgenic approaches. Furthermore, due to its relatively large size and metabolic homogeneity, the potato tuber represents a convenient experimental system for biochemical studies (Geigenberger 2003a).

In this chapter we will describe transgenic attempts to modify starch content and structure in potato tubers that have been carried out in the last two decades. In addition to describing biotechnologically significant results we will also detail fundamental research in this area that should enable future biotechnology strategies. However, we will begin by briefly describing starch, its structure, and its synthesis.

WHAT IS STARCH?

For many years, it has been recognized that the majority of starches consist of two different macromolecules, amylose and amylopectin (Fig. 32.1), which are both polymers of glucose and are organized into grains that range in size from 1 μm to more than 100 μm. Amylose is classically regarded as an essentially linear polymer wherein the glucose units are linked through α-1-4-glucosidic bonds. In contrast, although amylopectin contains α-1-4-glucosidic bonds, it also consists of a high proportion of α-1-6-glucosidic bonds. This feature of amylopectin makes it a more branched, larger molecule than amylose, having a molecular weight of 10^7–10^8 as opposed to 5×10^5–10^6.

Table 32.1. Industrial Uses of Starch

Starch and Its Derivates	Processing Industry	Application
Amylose and amylopectin (polymeric starch)	Food	Thickener, texturants, extenders, low-calorie snacks
	Paper	Beater sizing, surface sizing, coating
	Textile	Wrap sizing, finishing, printing
	Polymer	Absorbents, adhesives, biodegradable plastics
Products of starch hydrolysis, such as glucose, maltose, or dextrins	Food	Sweeteners or stabilizing agents
	Fermentation	Feedstock to produce ethanol, liquors, spirits, beer, etc.
	Pharmaceutical	Feedstock to produce drugs and medicine
	Chemical	Feedstock to produce organic solvents or acids

Source: Adapted from Jansson et al. 1997, with modification.

These molecules can thus be fractionated by utilizing differences in their molecular size as well as in their binding behavior. Moreover, amylose is able to complex lipids, while amylopectin can contain covalently bound phosphate, adding further complexity to their structure. In nature, amylose normally accounts between 20 and 30% of the total starch. However, the percentage of amylose depends on the species and the organ used for starch storage. The proportion of amylose to amylopectin and the size and structure of the starch grain give distinct properties to different extracted starches (properties important in food and industrial purposes; Dennis and Blakeley 2000). Starch grain size is also dependent on species and organ type. It is well established that starch grains grow by adding layers, and growth rings within the grain may represent areas of fast and slower growth (Pilling and Smith 2003); however, very little is known about how these highly ordered structures are formed in vivo. The interested reader is referred to articles by Buleon et al. (1998) and Kossmann and Lloyd (2000).
Figure 32.1. Starch structure: Amylose (**A**) is classically regarded as an essentially linear polymer wherein the glucose units are linked through α-1-4-glucosidic bonds. In contrast, although amylopectin contains α-1-4-glucosidic bonds, it also consists of a high proportion of α-1-6-glucosidic bonds (**B**).

ROUTES OF STARCH SYNTHESIS AND DEGRADATION AND THEIR REGULATION

With the possible exception of sucrose, starch is the most important metabolite of plant carbohydrate metabolism. It is by far the most dominant storage polysaccharide and is present in all major organs of most plants, in some instances at very high levels. Due to the high likelihood of starch turnover, its metabolism is best considered as the balance between the antagonistic operation of pathways of synthesis and degradation.

To investigate the regulation of starch synthesis in more detail, growing potato tubers have been used as a model system. Unlike many other tissues, the entry of sucrose into metabolism is relatively simple, in that it is unloaded symplasmically from the phloem, degraded via sucrose synthase to fructose and UDPglucose, which are converted to hexose monophosphates by fructokinase and UDPglucose pyrophosphorylase, respectively (Geigenberger 2003a). In contrast to sucrose degradation, which is localized in the cytosol, starch is synthesized predominantly, if not exclusively, in the plastid. The precise pathway of starch synthesis depends on the form in which carbon crosses the amyloplast membrane (Fig. 32.2). This varies between species and has been the subject of considerable debate (Keeling et al. 1988, Hatzfeld and Stitt 1990, Tauberger et al. 2000). Categorical evidence that carbon enters potato tuber, *Chenopodium rubrum* suspension cell, maize endosperm, and wheat endosperm amy-

loplasts in the form of hexose monophosphates rather than triose phosphates was provided by determination of the degree of randomization of radiolabel in glucose units isolated from starch following incubation of the various tissues with glucose labeled at the C1 or C6 positions (Keeling et al. 1988, Hatzfeld and Stitt 1990). The cloning of a hexose monophosphate transporter from potato and the finding that the cauliflower homolog is highly specific for glucose-6-phosphate provides strong support for this theory (Kammerer et al. 1998). Further evidence in support of glucose-6-phosphate import was provided by studies of transgenic potato lines in which the activity of the plastidial isoform of phosphoglucomutase was reduced by antisense inhibition, leading to a large reduction in starch content of the tubers (Tauberger et al. 2000). These data are in agreement with the observations that heterotrophic tissues lack plastidial fructose-1,6-bisphosphatase expression and activity (Entwistle and Rees 1990, Kossmann et al. 1992). The results of recent transgenic and immunolocalization experiments have indicated that the substrate for uptake is most probably species specific, with clear evidence for the predominant route of uptake in the developing potato tuber being in the form of glucose-6-phosphate. By contrast, in barley, wheat, oat, and possibly maize, the predominant form of uptake, at least during early stages of seed endosperm development, is as ADP-glucose (Neuhaus and Emes 2000).

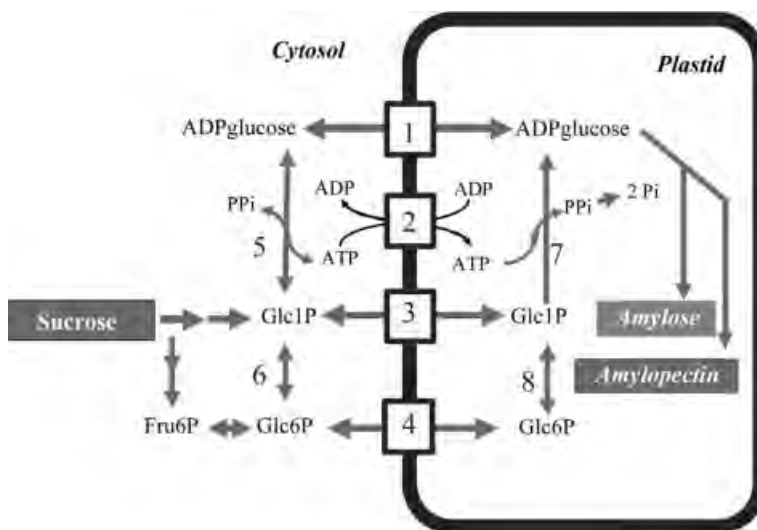
Irrespective of the route of carbon import, ADP-glucose pyrophosphorylase (AGPase, EC 2.7.7.27) plays an important role in starch synthesis, catalyzing the conversion of


Figure 32.2. Pathways of sucrose to starch conversion in plants: **1**, ADP-glucose transporter; **2**, ATP/ADP translocator; **3**, glucose-1-phoshate (Glc1P) translocator; **4**, glucose-6-phosphate (Glc6P) translocator; **5**, cytosolic ADP-glucose pyrophosphorylase (AGPase); **6**, cytosolic phosphoglucomutase; **7**, plastidial AGPase; **8**, plastidial phosphoglucomutase. In growing potato tubers, incoming sucrose is degraded by sucrose synthase to fructose and UDPglucose and subsequently converted to fructose-6-phosphate (Fru6P) and Glc1P by fructokinase and UDPglucose pyrophosphorylase, respectively (not shown in detail). The conversion of Fru6P to Glc6P in the cytosol is catalyzed by phosphoglucoisomerase, and the cleavage of PP_i to 2 P_i in the plastid is catalyzed by inorganic pyrophosphatase. In potato tubers, there is now convincing evidence that carbon enters the plastid almost exclusively via the Glc6P translocator, whereas in cereal endosperm, the predominant form of uptake is as ADPglucose.
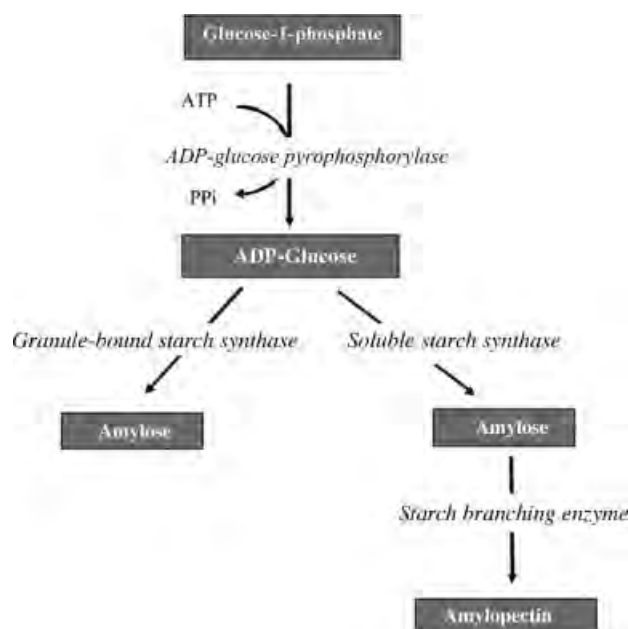

Figure 32.3. Routes of amylose and amylopectin synthesis within potato tuber amyloplasts. For simplicity, the possible roles of starch-degrading enzymes in trimming amylopectin have been neglected in this scheme.

glucose-1-phosphate and ATP to ADP-glucose and inorganic pyrophosphate. Inorganic pyrophosphate is subsequently metabolized to inorganic phosphate by a highly active inorganic pyrophosphatase within the plastid. AGPase is generally considered as the first committed step of starch biosynthesis since it produces ADP-glucose, the direct precursor for the starch polymerizing reactions catalyzed by starch synthase (SS) (EC 2.4.1.21) and branching enzyme (EC 2.4.1.24; Fig. 32.3). These three enzymes appear to be involved in starch synthesis in all species. With the exceptions of the cereal species described above, which also have a cytosolic isoform of AGPase, these reactions are confined to the plastid. The activities of AGPase and SS are sufficient to account for the rates of starch synthesis in a wide variety of photosynthetic and heterotrophic tissues (Smith et al. 1997). Furthermore, changes in the activities of these enzymes correlate with changes in the accumulation of starch during development of storage organs (Smith et al. 1995). AGPase from a range of photosynthetic and heterotrophic tissues is well established to be inhibited by phosphate, which induces sigmoidal kinetics, and to be allosterically activated by 3-phosphoglycerate (3PGA), which relieves phosphate inhibition (Preiss 1988; Fig. 32.4). There is clear evidence that allosteric regulation of AGPase is important in vivo to adjust the rate of starch synthesis to changes in the rate of respiration that go along with changes in the levels of 3PGA, and an impressive body of evidence has been provided that there is a strong correlation between the 3PGA and ADP-glucose levels and the rate of starch synthesis under a wide

variety of environmental conditions (Geigenberger et al. 1998, Geigenberger 2003a).

More recently, an important physiological role for posttranslational redox regulation of AGPase has been established (Tiessen et al. 2002). In this case, reduction of an intermolecular cysteine bridge between the two small subunits of the heterotetrameric enzyme leads to a dramatic increase of activity, due to increased substrate affinities and sensitivity to allosteric activation by 3PGA (Fig. 32.4). Redox activation of AGPase *in planta* correlated closely with the potato tuber sucrose content across a range of physiological and genetic manipulations (Tiessen et al. 2002), indicating that redox modulation is part of a novel regulatory loop that directs incoming sucrose towards storage starch synthesis (Tiessen et al. 2003). Crucially, it allows the rate of starch synthesis to be increased in response to sucrose supply and independently of any increase in metabolite levels (Fig. 32.4), and it is therefore an interesting target for approaches to improving starch yield (see later). There are at least two separate sugar signaling pathways leading to posttranslational redox activation of AGPase, one involving an SNF1-like protein kinase (SnRK1), the other involving hexokinase (Tiessen et al. 2003). Both hexokinase and SnRK1 have previously been shown to be involved in the transcriptional regulation of many plant genes. Obviously, the transduction pathway that regulates the reductive activation of AGPase in plastids and the regulatory network that controls the expression of genes in the cytosol share some common components. How the sugar signal is transferred into the plastid and leads to redox changes of AGPase is still unknown, but may involve interaction of specific thioredoxins with AGPase.

Subcellular analyses of metabolite levels in growing potato tubers have shown that the reaction catalyzed by AGPase is far from equilibrium in vivo (Tiessen et al. 2002), and consequently, the flux through this enzyme is particularly sensitive to regulation by the above-mentioned factors. It is interesting to note that plants contain multiple forms of AGPase, which is a tetrameric enzyme comprising two different polypeptides, a small subunit and a large subunit, both of which are required for full activity (Preiss 1988). Both subunits are encoded by multiple genes, which are differentially expressed in different tissues. Although the precise function of this differential expression is currently unknown, it seems likely that these isoforms will differ in their capacity to bind allosteric regulators. If this is indeed the case, then different combinations of small and large subunits should show different sensitivity to allosteric regulation—such as those observed in tissues from cereals.

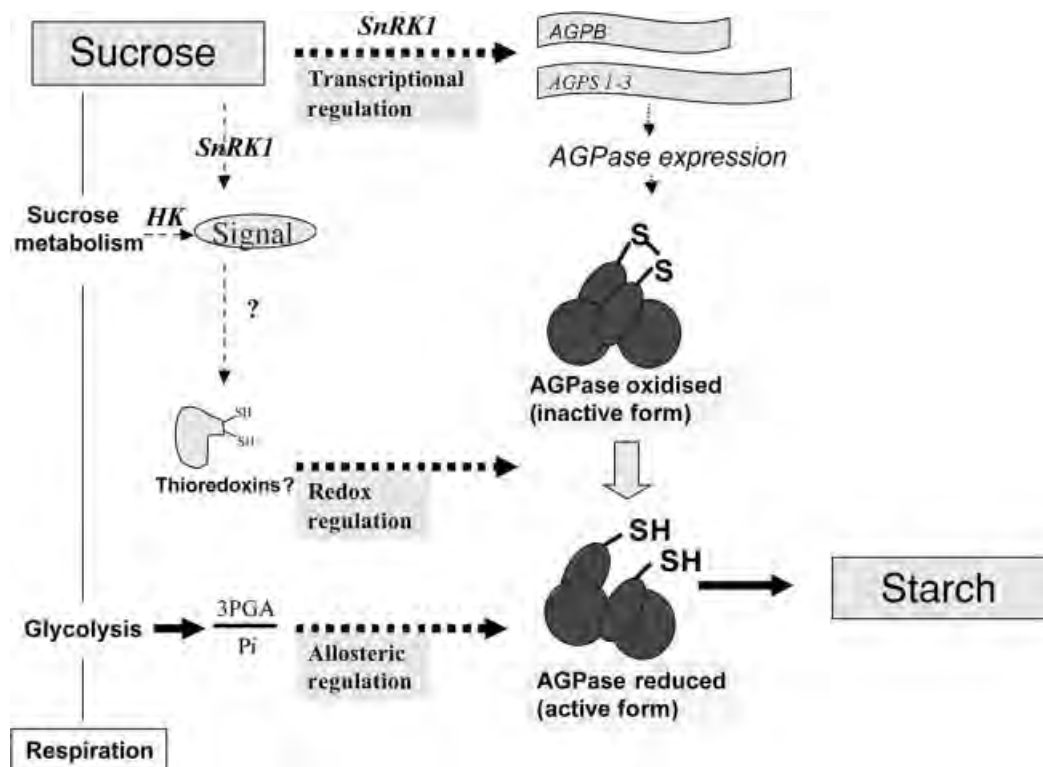
While there is a wealth of information on the regulation of the plastidial isoforms of AGPase—the only isoform present in the potato tuber—very little is known about cytosolic isoforms in other species. Several important studies provide evidence that the ADP-glucose produced in the cytosol can be taken up by the plastid (Sullivan et al. 1991, Shannon et al. 1998). From these studies and from characterization of mutants unable to transport ADP-glucose, it would appear that this is a predominant route for starch synthesis within maize. Despite these findings, the physiological significance of cytosolic ADP-glucose production remains unclear for a range of species. However, it has been calculated that the AGPase activity of the plastid is insufficient


Figure 32.4. Regulation of starch synthesis in potato tubers: ADPGlc-pyrophosphorylase (AGPase) is a key regulatory enzyme of starch biosynthesis. It is regulated at different levels of control, involving allosteric regulation, regulation by posttranslational redox modification and transcriptional regulation. Redox regulation of AGPase represents a novel mechanism regulating starch synthesis in response to changes in sucrose supply (Tiessen et al. 2002). There are at least two separate sugar-sensing pathways leading to posttranslational redox activation of AGPase, one involving an SNF1-like protein kinase (SnRK1), the other involving hexokinase (HK) (Tiessen et al. 2003).

to account for the measured rates of starch synthesis in barley endosperm, suggesting that at least some of the ADP-glucose required for this process is provided by cytosolic production (Thorbjornsen et al. 1996).

It is interesting to note that the involvement of the various isoforms of AGPase in starch biosynthesis is strictly species dependent, whereas the various starch-polymerizing activities are ever present and responsible for the formation of the two different macromolecular forms of starch, amylose and amylopectin (Fig. 32.3). SS catalyze the transfer of the glucosyl moiety from ADP-glucose to the nonreducing end of an α-1,4-glucan and are able to extend α-1,4-glucans in both amylose and amylopectin. There are four different SS isozymes—three soluble and one that is bound to the starch granule.

Starch branching enzymes (SBE), meanwhile, are responsible for the formation of α-1,6 branch points within amylopectin (Fig. 32.3). The precise mechanism by which this is achieved is unknown; however, it is thought to involve cleavage of a linear α-1,4-linked glucose chain and reattachment of the chain to form an α-1,6 linkage. Two isozymes of starch branching enzyme, SBEI and SBEII, are present and differ in specificity. The former preferentially branches unbranched starch (amylose), while the

latter preferentially branches amylopectin. Furthermore, in vitro studies indicate that SBEII transfers smaller glucan chains than does SBEI and would therefore be expected to create a more highly branched starch (Schwall et al. 2000). The fact that the developmental expression of these isoforms correlates with the structural properties of starch during pea embryo development is in keeping with this suggestion (Smith et al. 1997). Apart from that, isoforms of isoamylase (E.C. 3.2.1.68) might be involved in debranching starch during its synthesis (Smith et al. 2003).

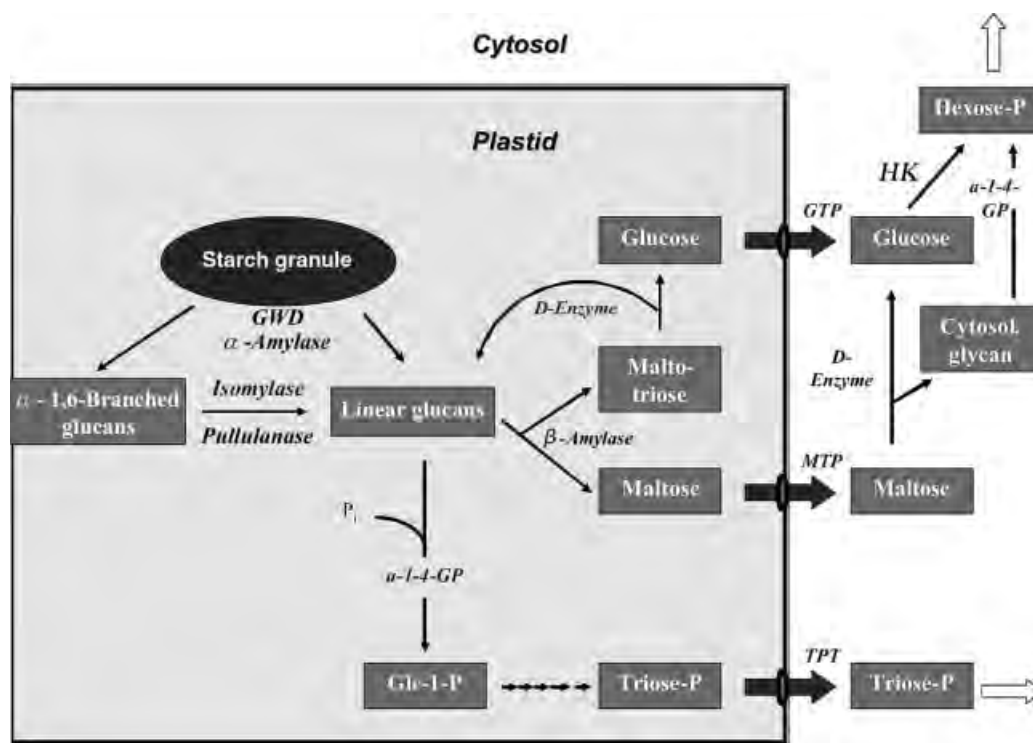
While the pathways governing starch synthesis are relatively clear, those associated with starch degradation remain somewhat controversial (Smith et al. 2003). The degradation of plastidial starch can proceed via phosphorolytic or hydrolytic cleavage mechanisms involving α-1-4-glucan phosphorylases or amylases, respectively. The relative importance of these different routes of starch degradation has been a matter of debate for many years. The question is whether they are, in fact, independent pathways, since oligosaccharides released by hydrolysis can be further degraded by amylases or, alternatively, by phosphorylases. In addition to this, the mechanisms responsible for the initiation of starch grain degradation in the plastid remain to be resolved, since starch grains have been found to


Figure 32.5. Outline of the pathway of plastidial starch degradation. The scheme is mainly based on recent molecular studies in *Arabidopsis* leaves (Ritte et al. 2002, Smith et al. 2003, Chia et al. 2004). After phosphorylation of glucans on the surface of the starch granule via glucan water dikinase (GWD; R1-protein), starch granules are attacked most probably by α-amylase and the resulting branched glucans subsequently converted to unbranched α-1,4-glucans via debranching enzymes (isoamylase and pullulanase). Linear glucans are metabolized by the concerted action of β-amylase and disproportionating enzyme (D-enzyme, glucan transferase) to maltose and glucose. The phosphorolytic degradation of linear glucans to Glc-1-P (glucose-1-phosphate) by α-1-4-glucan phosphorylase (α-1-4-GP) is also possible, but seems of minor importance under normal conditions. Most of the carbon resulting from starch degradation leaves the chloroplast via a maltose transporter in the inner membrane. Subsequent cytosolic metabolism of maltose involves the combined action of glucan transferase (D-enzyme), α-1-4-glucan phosphorylase (α-1-4-GP), and hexokinase (HK). Glucose transporter (GTP) and triose-P/P$_i$-translocator (TPT) are also shown.

be very stable and relatively resistant against enzymatic action in vitro.

More recently, molecular and genetic approaches have allowed rapid progress in clarifying the route of starch degradation in leaves of the model species *Arabidopsis thaliana* (Fig. 32.5). The phosphorylation of starch granules by glucan water dikinase (GWD, R1) has been found to be essential for the initiation of starch degradation in leaves and tubers (Ritte et al. 2002, Ritte et al. 2004). Transgenic potato plants (Lorberth et al. 1998) and *Arabidopsis* mutants (Yu et al. 2001) with decreased GWD activity showed a decrease in starch-bound phosphate and were severely restricted in their ability to degrade starch, leading to increased starch accumulation in leaves. The underlying mechanisms are still unknown. Phosphorylation of starch may change the structure of the granule surface to make it more susceptible to enzymatic attack or may regulate the extent to which degradative enzymes can attack the granule.

It is generally assumed that the initial attack on the starch granule is catalyzed by α-amylase (endoamylase). This enzyme

catalyzes the internal cleavage of glucan chains from amylose or amylopectin, yielding branched and unbranched α-1,4-glucans, which are then subject to further digestion (Fig. 32.5). Debranching enzymes (isoamylase and pullulanase) are needed to convert branched glucans into linear glucans by cleaving the α-1,6 branch points. Further metabolism of linear glucans could involve phosphorolytic or hydrolytic routes. In the first case, α-glucan phosphorylase leads to the phosphorolytic release of Glc1-P, which can be further metabolized to triose-P within the chloroplast and subsequently exported to the cytosol via the triose-P/P$_i$ translocator. Recent results show that the contribution of α-glucan phosphorylase to plastidial starch degradation is relatively small. Removal of the plastidial form of phosphorylase in *Arabidopsis* did not affect starch degradation in leaves of *Arabidopsis* (Zeeman et al. 2004) and potato (Sonnewald et al. 1995). It has been suggested that the phosphorolytic pathway could be more important to degrading starch under certain stress conditions (i.e., water stress; Zeeman et al. 2004). However, no regulatory properties have been described for glucan

phosphorylase in plants, other than the effect of changes in the concentrations of inorganic phosphate on the activity of the enzyme (Stitt and Steup 1985).

In the second case, hydrolytic degradation of linear glucans in the plastid can involve the combined four action enzymes: α-amylase, β-amylase, α-glucosidase and disproportionating enzyme (D-enzyme, glucan transferase). There is now direct molecular evidence that β-amylase (exoamylase) plays a significant role in this process (Scheidig et al. 2002). This enzyme catalyzes the hydrolytic cleavage of maltose from the nonreducing end of a linear glucan polymer that is larger than maltotriose. Maltotriose is further metabolized by D-enzyme, producing new substrate for β-amylase and releasing glucose (Fig. 32.5).

Recent studies document that most of the carbon that results from starch degradation leaves the chloroplast in the form of maltose, providing evidence that hydrolytic degradation is the major pathway for mobilization of transitory starch (Weise et al. 2004). Elegant studies with *Arabidopsis* mutants confirmed this interpretation and identified a maltose transporter in the chloroplast envelope that is essential for starch degradation in leaves (Niittylä et al. 2004). The further metabolism of maltose to hexose-phosphates is then performed in the cytosol and is proposed to involve cytosolic forms of glycosyltransferase (D-enzyme; Lu and Sharkey 2004, Chia et al. 2004), α-glucan phosphorylase (Duwenig et al. 1997), and hexokinase, similar to maltose metabolism in the cytoplasm of *E. coli* (Boos and Shuman 1998). It will be interesting to find the potato homolog of the maltose transporter and to investigate its role during starch degradation in tubers.

Despite recent progress in clarifying the route of starch degradation in *Arabidopsis* leaves and potato tubers, the regulation of this pathway still remains an open question. More information is available concerning cereal seeds, where the enzymes involved in starch hydrolysis have been found to be especially active during seed germination, when starch is mobilized within the endosperm, which at this stage of development represents a nonliving tissue. The most studied enzyme in this specialized system is α-amylase, which is synthesized in the surrounding aleurone layer and secreted into the endosperm. This activity and that of α-glucosidase increase in response to the high levels of gibberellins present at germination. A further level of control of the amylolytic pathway is achieved by the action of specific disulphide proteins that inhibit both α-amylase and debranching enzyme. Thioredoxin *h* reduces and thereby inactivates these inhibitor proteins early in germination. Glucose liberated from starch in this manner is phosphorylated by a hexokinase, before conversion to sucrose and subsequent transport to the developing embryo (Beck and Ziegler 1989).

MANIPULATION OF STARCH YIELD

In potato tubers, like all crop species, there has been considerable interest to increase the efficiency of sucrose to starch conversion and thus to increase starch accumulation by both conventional plant breeding and genetic manipulation strategies. Traditional methodology based on the crossing of haploid potato lines and the establishment of a high density genetic map have allowed the identification of quantitative trait loci (QTL) for starch content (Schäfer-Pregl et al. 1998); however, this is outside the scope of this chapter, and the interested reader is referred to Fernie and Willmitzer (2001). Transgenic approaches in potato have focused primarily on the modulation of sucrose import (Leggewie et al. 2003) and sucrose mobilization (Trethewey et al. 1998) or the plastidial starch biosynthetic pathway (see Table 32.2); however, recently more indirect targets have been tested, which are mostly linked to the supply of energy for starch synthesis (see Tjaden et al. 1998, Jenner et al. 2001, Regierer et al. 2002). To date, the most successful transgenic approaches have resulted from the overexpression of a bacterial AGPase (Stark et al. 1991) and the *Arabidopsis* plastidial ATP/ADP translocator (Tjaden et al. 1998), and the antisense inhibition of a plastidial adenylate kinase (Regierer et al. 2002) in potato tubers.

The majority of previous attempts to improve the starch yield of potato tubers concentrated on the expression of a more efficient pathway of sucrose degradation, consisting of a yeast invertase, a bacterial glucokinase, and a sucrose phosphorylase (Trethewey et al. 1998, 2001). However, although the transgenics exhibited decreased levels of sucrose and elevated hexose phosphates and 3-PGA with respect to wild type, these attempts failed. Tubers of these plants even contained less starch than the wild type, but showed higher respiration rates. Recent studies have shown that as a consequence of the high rates of oxygen consumption, oxygen tensions fall to almost zero within growing tubers of these transformants, possibly as a consequence of the high energy demand of the introduced pathway, and this results in a dramatic decrease in the cellular energy state (Bologa et al. 2003, Geigenberger 2003b). This decrease is probably the major reason for the unexpected observation that starch synthesis decreases in these lines. In general, oxygen can fall to very low concentrations in developing sink organs like potato tubers and seeds, even under normal environmental conditions (Geigenberger 2003b, Vigeolas et al. 2003, van Dongen et al. 2004). The consequences of these low internal oxygen concentrations for metabolic events during storage product formation have been ignored in metabolic engineering strategies. Molecular approaches to increase internal oxygen concentrations could provide a novel and exiting route for crop improvement.

Another failed attempt at increasing tuber starch accumulation was the overexpression of a heterologous sucrose transporter from spinach under the control of the CaMV 35S promoter (Leggewie et al. 2003). The rationale behind this attempt was that it would increase carbon partitioning toward the tuber; however, in the absence of improved photosynthetic efficiency this was not the case.

With respect to the plastidial pathway for starch synthesis, much attention has been focused on AGPase. Analysis of potato lines exhibiting different levels of reduction of AGPase due to antisense inhibition have been used to estimate flux control coefficients for starch synthesis of between 0.3 and 0.55 for this enzyme (Geigenberger et al. 1999a, Sweetlove et al. 1999), showing that AGPase is collimating for starch accumulation in potato tubers. In addition to having significantly reduced starch content in the tubers, these lines also exhibit very high tuber sucrose content, produce more but smaller tubers per plant, and

Table 32.2. Summary of Transgenic Approaches to Manipulate Starch Structure and Yield in Potato Tubers

Target	Transgenic Approach	Starch Content/ Yield	Starch Structure	Grain/Tuber Morphology	Application	Reference
Plastidial ATP/ADP translocator	Antisense inhibition	Starch content decreased to 20%	Less amylose	Grains size decreased to 50%, strange tuber shape	—	Tjaden et al. 1998
Plastidial ATP/ADP translocator	Overexpression of AATP	Starch content increased by up to 30%	More amylose	Grains with angular shape	High starch with more amylose	Tjaden et al. 1998, Geigenberger et al. 2001
Plastidial adenylate kinase	Antisense inhibition	Starch content and yield increased by up to 60%	Not determined	Not determined	High starch	Regierer et al. 2003
ADPGlc pyro-phosphorylase	Antisense inhibition of AGPB	Starch content decreased down to 10% of WT-level	Amylose content decreased by 40%	Smaller grains, smaller tubers, increased tuber number	—	Müller-Röber et al. 1992, Lloyd et al. 1999b
ADPGlc pyro-phosphorylase	Overexpression of glgC	Starch content increased by up to 30%	Not determined	Not determined	High starch	Stark et al. 1991
Granule bound starch synthase	Antisense inhibition of GBSSI	No effect	Starch is free of amylose	No effect	Amylose free starch	Kuipers et al. 1994

Enzyme	Manipulation	Yield	Starch composition	Granule morphology	Property	Reference
Granule-bound starch synthase	Overexpression of GBSS I	No effect	Amylose increased up to 25.5%	No effect	—	Kuipers et al. 1994
Soluble starch synthase	Antisense inhibition of SS III	No effect	Amylopectin chain length altered, more P in starch	Granules cracked with deep fissures	—	Abel et al. 1996, Marshall et al. 1996; Fulton et al. 2002
Soluble and granule-bound starch synthases	Antisense inhibition of GBSS I, SS II & SS III	No effect	Less amylose, shorter amylopectin chains	Concentric granules	Freeze/thaw- stable starch	Jobling et al. 2002, Fulton et al. 2002
Starch branching enzymes	Antisense inhibition of SBE I and SBE II	Decreased yield	Amylose increased to >70%, low amylopectin, five-fold more P in starch.	Granule morphology altered	High amylose and high P starch	Schwall et al. 2000
Starch water dikinase (R1)	Antisense inhibition of R1	No effect	Less P in starch	Not determined	Low P starch	Lorberth et al. 1998

produce smaller starch grains than the wild type (Müller-Röber et al. 1992; see also later discussion and Table 32.2). To date, one of the most successful approaches for elevating starch accumulation in tubers was that of Stark et al. (1991), who overexpressed an unregulated bacterial AGPase. This manipulation resulted in up to a 30% increase in tuber starch content. However, it should be noted that the expression of exactly the same enzyme within a second potato cultivar did not significantly affect starch levels (Sweetlove et al. 1996), indicating that these results might be highly context dependent. Another more promising route to increase starch yield would be to manipulate the regulatory network leading to posttranslational redox activation of AGPase (see Fig. 32.4). Based on future progress in this field, direct strategies can be taken to modify the regulatory components leading to redox regulation of starch synthesis in potato tubers.

More recent studies have shown that the adenylate supply to the plastid is of fundamental importance to starch biosynthesis in potato tubers (Loef et al. 2001, Tjaden et al. 1998). Overexpression of the plastidial ATP/ADP translocator resulted in increased tuber starch content, whereas antisense inhibition of the same protein resulted in reduced starch yield, modified tuber morphology, and altered starch structure (Tjaden et al. 1998). Furthermore, incubation of tuber discs in adenine resulted in a considerable increase in cellular adenylate pool sizes and a consequent increase in the rate of starch synthesis (Loef et al. 2001). The enzyme adenylate kinase (EC 2.7.4.3) interconverts ATP and AMP into 2 ADP. Because adenylate kinase is involved in maintaining the levels of the various adenylates at equilibrium, it represents an interesting target for modulating the adenylate pools in plants. For this reason, a molecular approach was taken to downregulate the plastidial isoform of this enzyme by the antisense technique (Regierer et al. 2002). This manipulation led to a substantial increase in the levels of all adenylate pools (including ATP) and, most importantly, to a record increase in tuber starch content up to 60% above wild type. These results are particularly striking because this genetic manipulation also resulted in a dramatic increase in tuber yield during several field trials of approximately 40% higher than that of the wild type. When taken in tandem, these results suggest a doubling of starch yield per plant. In addition to the changes described above, more moderate increases in starch yield were previously obtained by targeting enzymes esoteric to the pathway of starch synthesis, for example, plants impaired in their expression of the sucrose synthetic enzyme, sucrose phosphate synthase (Geigenberger et al. 1999b). This enzyme exerts negative control on starch synthesis since it is involved in a futile cycle of sucrose synthesis and degradation and leads to a decrease in the net rate of sucrose degradation in potato tubers (Geigenberger et al. 1997).

Although these results are exciting from a biotechnological perspective and they give clear hints as to how starch synthesis is coordinated in vivo, they do not currently allow us to establish the mechanisms by which they operate. It is also clear that these results, while promising, are unlikely to be the only way to achieve increases in starch yield. Recent advances in transgenic technologies now allow the manipulation of multiple targets in tandem (Fernie et al. 2001), and given that several of the successful manipulations described above were somewhat unexpected, the possibility that further such examples will be uncovered in the future cannot be excluded. One obvious future target would be to reduce the expression levels of the starch degradative pathway since, as described above, starch content is clearly a function of the relative activities of the synthetic and degradative pathways. Despite the fact that a large number of *Arabidopsis* mutants has now been generated that are deficient in the pathway of starch degradation, the consequence of such deficiencies has not been investigated in a crop such as potato tubers. Furthermore, there are no reports to date of increases in starch yield in heterotrophic tissues displaying mutations in the starch degradative pathway.

A further phenomenon in potatoes that relates to starch metabolism is that of cold-induced sweetening, where the rate of degradation of starch to reducing sugars is accelerated. As raw potatoes are sliced and cooked in oil at high temperature, the accumulated reducing sugars react with free amino acids in the potato cell, forming unacceptably brown- to black-pigmented chips or fries via a nonenzymatic, Maillard-type reaction. Potatoes yielding these unacceptably colored products are generally rejected for purchase by the processing plant. If a "cold-processing potato" (i.e., one which has low sugar content even in the cold) were available, energy savings would be realized in potato-growing regions where outside storage temperatures are cool. In regions where outside temperatures are moderately high, increased refrigeration costs may occur. This expense would be offset, however, by removal of the need to purchase dormancy-prolonging chemicals, by a decreased need for disease control, and by improvement of long-term tuber quality. Although such a cold-processing potato is not yet on the market, several manipulations potentially fulfill this criterion, perhaps most impressively the antisense inhibition of GWD, which is involved in the initiation of starch degradation (Lorberth et al. 1998). Further examples on this subject are excellently reviewed in a recent paper by Sowokinos (2001).

While only a limited number of successful manipulations of starch yield have been reported to date, far more successful manipulations have been reported with respect to engineering starch structure. These will be reviewed in Section "Manipulation of Starch Structure."

MANIPULATION OF STARCH STRUCTURE

In addition to attempting to increase starch yield, there have been many, arguably more, successful attempts to manipulate its structural properties. Considerable natural variation exists between the starch structures of crop species, with potato starch having larger granules, less amylose, a higher proportion of covalently bound phosphate, and less protein and lipid content than cereal starches. The level of phosphorylation strongly influences the physical properties of starch, and granule size is another important factor for many applications; for example, determining starch noodle processing and quality (Jobling et al. 2004). In addition, the ratio between the different polymer types can affect the functionality of different starches (Slattery et al. 1998). High amylose starches are used in fried snack products to create crisp

and evenly brown snacks, as gelling agents, and in photographic films, whereas high amylopectin starches are useful in the food industry (to improve uniformity, stability, and texture) and in the paper and adhesive industries. Both, conventional breeding and transgenic approaches have been utilized for modification of starch properties (specifically amylose, amylopectin, and phosphate content; Sene et al. 2000, Kossmann and Lloyd 2000). However, in contrast to the situation described previously for yield, the use of natural mutants has been far more prevalent in this instance.

QTL analyses have recently been adopted for identifying the genetic factors underlying starch structure. Recombinant inbred lines were produced from parental maize lines of differing starch structure, and the amylose, amylopectin, and water-soluble fractions were analyzed. The loci linked to these traits were located on a genetic map consisting of RFLP (restriction fragment length polymorphism) markers (Sene et al. 2000). Using this strategy, candidate genes were identified that influenced starch structure. It is clear that application of these techniques may facilitate future breeding approaches to generate modified starch properties.

In addition to plant breeding approaches the use of transgenesis has been of fundamental importance for understanding and influencing starch structure (see Table 32.2). Potato tubers with decreased expression of AGPase (Müller-Röber et al. 1992) had decreased amylose contents, down to about 60% of that found in wild type, and smaller starch granules (Lloyd et al. 1999b). The reduction in amylose content is most likely due to the decreased levels of ADP-glucose found in these plants, since this leads to selective restriction of granule-bound versus soluble SSs, the latter having a higher affinity for ADPGlc (Frydman and Cardini 1967). Similarly, when the plastidial adenylate supply was altered by changes in the expression of the amyloplastidial ATP/ADP translocator, not only the starch content, but also its structural properties were altered (Tjaden et al. 1998, Geigenberger et al. 2001). Tubers of ATP/ADP-translocator overexpressing lines had higher levels of ADP-glucose and starch with higher amylose content, whereas the opposite was true for antisense lines. Furthermore, microscopic examination of starch grains revealed that their size in antisense tubers was considerably decreased (by 50%) in comparison with the wild type.

Antisensing granule-bound SS I (GBSSI) in potato tubers resulted in a starch that was almost free of amylose (Kuipers et al. 1994). This type of starch has improved paste clarity and stability with potential applications in the food and paper industries (Jobling 2004). In contrast to this, the amylose content of potato starch could not be increased above a value of 25.5% on overexpression of GBSS, hinting that this enzyme is not limiting in amylose production (Flipse et al. 1994, 1996). It has additionally been demonstrated that amylose can be completely replaced by a branched material that exhibits properties in between those of amylose and amylopectin following plastid-targeted expression of bacterial glycogen synthases (Kortstee et al. 1998).

The roles of the other isoforms of starch synthase (SS) are, if anything, less clear. A dramatic reduction in the expression of SSI in potato had absolutely no consequences on starch structure (Kossmann et al. 1999). The effects of modifying SSII were

observed in pea seeds mutated at the *rug*5 locus, which encodes this protein. These mutants display a wrinkled phenotype that is often caused by decreased embryo starch content. Starch granules in these plants exhibit a striking alteration in morphology in that they have a far more irregular shape and exhibit a reduction in medium chain length glucans coupled to an increase in short- and long-chain glucans. Despite the dramatic changes observed in the pea mutant, the down-regulation of SSII in the potato tuber had only minor effects, including a 50% reduction in the phosphate content of the starch and a slight increase in short chain length glucans (Kossmann et al. 1999, Lloyd et al. 1999a). However, it is worth noting that SSII only contributes 15% of the total soluble SS activity within the tuber. Finally, a third class of SS has also been identified and has been reported to be the major form in potato tubers (Marshall et al. 1996). When this isoform (SSIII) was downregulated by the creation of transgenic potato plants, deep fissures were observed in the starch granule under the electron microscope, most probably due to GBSS making longer glucan chains in this background (Fulton et al. 2002). However, the starch was not altered in its amylose content, nor did it display major differences in chain length distribution of short chains within the amylopectin (Marshall et al. 1996, Lloyd et al. 1999a). However, dramatic changes were observed when the structure of the side chains was studied, with an accumulation of shorter chains observed in the transgenic lines (Lloyd et al. 1999a). In addition to this, the phosphate content of the starch was doubled in this transformant (Abel et al. 1996).

Given that some of the changes observed on alteration of a single isoform of SS were so dramatic, several groups have looked into the effects of simultaneously modifying the activities of more than one isoform by the generation of chimeric antisense constructs. When potato tubers were produced in which the activities of SSII and SSIII were simultaneously repressed (Edwards et al. 1999, Lloyd et al. 1999b), the effects were not additive. The amylopectin from these lines was somewhat different from that resulting from inhibition of the single isoforms, with the double antisense plants exhibiting grossly modified amylopectin consisting of more short and extra long chains but fewer medium length chains, leading to a gross alteration in the structure of the starch granules. In another study, the parallel reduction of GBSSI, SSII, and SSIII resulted in starch with less amylose and shorter amylopectin chains, which conferred additional freeze-thaw stability of starch with respect to the wild type (Jobling et al. 2002). This is beneficial since it replaces the necessity for expensive chemical substitution reactions, and in addition, its production may require less energy, as this starch cooks at much lower temperatures than normal potato starches.

Simultaneously inhibiting two isoforms of starch-branching enzyme to below 1% of the wild-type activities resulted in highly modified starch in potato tubers. In this starch, normal, high molecular weight amylopectin was absent, whereas the amylose content was increased to levels above 70%, comparable to that in the highest commercially available maize starches (Schwall et al. 2000; Table 32.2). There was also a major effect on starch granule morphology. In addition, the phosphorus content of the starch was increased more than five fold. This

unique starch, with its high amylose, low amylopectin, and high phosphorus levels, offers novel properties for food and industrial applications. A further example of altered phosphate starch is provided by research into potato plants deficient in GWD (previously known as R1, Lorberth et al. 1998, Ritte et al. 2002)). The importance of starch phosphorylation becomes clear when it is considered that starch phosphate monoesters increase the clarity and viscosity of starch pastes and decrease the gelatinization and retrogradation rate. Interestingly, crops that produce high-amylose starches are characterized by considerably lower yield (Jobling 2004). Additional transgenic or breeding approaches, as discussed in Section "Manipulation of Starch Yield" will be required to minimize the yield penalty that goes along with the manipulation of crops for altered starch structure and functionality.

As discussed previously for starch yield, the importance of starch degradative processes in determination of starch structural properties is currently poorly understood. However, it represents an interesting avenue for further research.

CONCLUSIONS AND FUTURE PERSPECTIVES

In this chapter we have reviewed the pathway organization of starch synthesis within the potato tuber and detailed how it can be modulated through transgenesis to result in higher starch yield or the production of starches of modified structure. While several successful examples exist for both types of manipulation, these are yet to reach the field. It is likely that such crops, once commercially produced, will yield both industrial and nutritional benefits to society. In addition to this, other genetic and biochemical factors may well also influence starch yield and structure, and further research is required in this area in order to fully optimize these parameters in crop species. In this context, transgenic approaches complementary to conventional breeding will allow more "fine-tuning" of starch properties.

Biochemistry of Beer Fermentation

Ronnie Willaert

Abstract: The carbohydrate metabolism and flavor formation during yeast primary and secondary fermentation (maturation) is reviewed. Carbohydrate metabolism and ethanol production during the primary fermentation is discussed firstly. Next, the metabolism of the bioflavoring by-product formation, that is, higher alcohols, esters, organic acids, and vicinal diketones, is elaborated. The next step of the fermentation process is the maturation process where the vicinal diketones, acetaldehyde, and hydrogen sulfide concentration needs to be reduced to acceptable levels. The chapter is concluded with a discussion about the use of immobilized cell tech-

nology to intensify the fermentation process and its impact on flavor production.

INTRODUCTION

The production of alcoholic beverages is as old as history. Wine may have an archeological record going back more than 7500 years, with the early suspected wine residues dating from early to mid-fifth millennium BC (McGovern et al. 1996). Clear evidence of intentional winemaking first appears in the representations of wine presses that date back to the reign of Udimu in Egypt, some 5000 years ago. The direct fermentation of fruit juices, such as that of grape, had doubtlessly taken place for many thousands of years before early thinking man developed beer brewing and, probably coincidentally, bread baking (Hardwick 1995). The oldest historical evidence of formal brewing dates back to about 6000 BC in ancient Babylonia is a piece of pottery found there, which shows workers either stirring or skimming a brewing vat.

Nowadays, alcoholic beverage production represents a significant contribution to the economies of many countries. The most important beverages today are beer, wine, distilled spirits, cider, sake, and liqueurs (Lea and Piggott 1995). In Belgium ("the beer paradise"), beer is the most important alcoholic beverage, although the beer consumption declined in the last 40 years: from 11,096,717 hL in 1965 to 9,703,000 hL in 2004 (NN 2005). In this time frame, wine consumption doubled from 1,059,964 to 2,215,579 hL. Another trend is the spectacular increase in waters and soft drinks consumption (from 5,215,056 to 26,395,000 hL).

In this chapter, the biochemistry and fermentation of beer is reviewed. First, the carbohydrate metabolism in brewer's yeast is discussed. The maltose metabolism is of major importance in beer brewing, since this sugar is in a high concentration present in wort. For the production of a high-quality beer, a well-controlled

fermentation needs to be performed. During this fermentation, major flavor-active compounds are produced (and some of them are again metabolized) by the yeast cells. The metabolism of the most important fermentation by-products during main and secondary fermentation is discussed in detail. The latest trend in beer fermentation technology is the process intensification using immobilized cell technology (ICT). This new technology is explained and some illustrative applications—on small and large scale—are discussed.

THE BEER BREWING PROCESS

The principal raw materials used to brew beer are water, malted barley, hops and yeast. The brewing process involves extracting and breaking down the carbohydrate from the malted barley to make a sugar solution (called "wort"), which also contains essential nutrients for yeast growth, and using this as a source of nutrients for "anaerobic" yeast growth. During yeast fermentation, simple sugars are consumed, releasing heat and producing ethanol and other flavoring metabolic by-products. The major

biological changes, which occur in the brewing process, are catalyzed by naturally produced enzymes from barley (during malting) and yeast. The rest of the brewing process largely involves heat exchange, separation, and clarification, which only produces minor changes in chemical composition when compared to the enzyme catalyzed reactions. Barley is able to produce all the enzymes that are needed to degrade starch, β-glucan, pentosans, lipids, and proteins, which are the major compounds of interest to the brewer. An overview of the brewing process is shown in Figure 33.1, where also the input and output flows are indicated. Table 33.1 gives a more detailed explanation of each step in the process.

CARBOHYDRATE METABOLISM—ETHANOL PRODUCTION

WORT CARBOHYDRATES UPTAKE AND METABOLISM

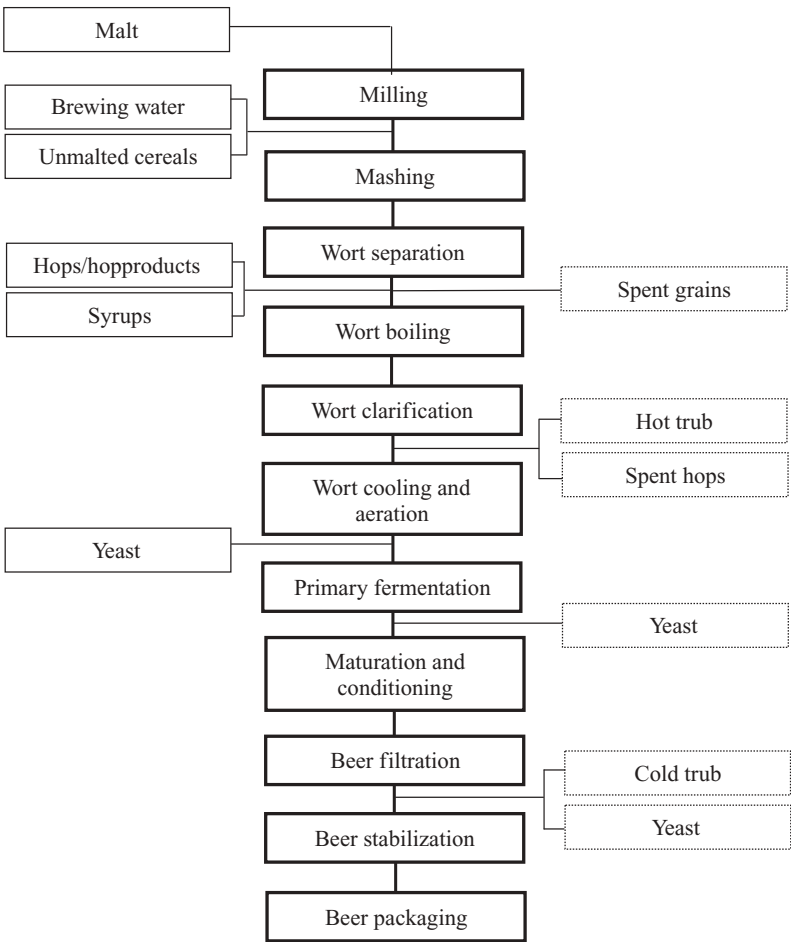
Carbohydrates in wort make up 90–92% of wort solids. Wort from barley malt contains the fermentable sugars sucrose, fructose, glucose, maltose, and maltotriose together with some


Figure 33.1. Schematic overview of the brewing process (input flows are indicated on the left side and output flows on the right side).

Table 33.1. Overview of the Brewing Processing Steps: From Barley to Beer

Process	Action	Objectives	Time	Temperature (°C)
Malting	Moistening and aeration of	Preparation for the germination	48 h	12–22
Steeping	barley	process	3–5 d	22
Germination	Barley germination	Enzyme production, chemical	24–48 h	22–110
Kilning	Kilning of the green malt	structure modification		
		Ending of germination and modification, production of flavoring and coloring substances		
Milling	Grain crushing without disintegrating the husks	Enzyme release and increase of surface area	1–2 h	22
Mashing + wort separation	Addition of warm/hot water	Stimulation of enzyme action, extraction and dissolution of compounds, wort filtration, to obtain the desired fermentable extract as quick as possible	1–2 h	30–72
Wort boiling	Boiling of wort and hops	Extraction and isomerization of hop components, hot break formation, wort sterilization, enzyme inactivation, formation of reducing, aromatic and coloring compounds, removal of undesired volatile aroma compounds, wort acidification, evaporation of water	0.5–1.5 h	>98
Wort clarification	Sedimentation or centrifugation	Removal of spent hops, clarification (whirlpool, centrifuge, settling tank)	<1 h	100–80
Wort cooling and aeration	Use of heat exchanger, injection of air bubbles	Preparing the wort for yeast growth	<1 h	12–18
Fermentation	Adding yeast, controlling the specific gravity, removal of yeast	Production of green beer, to obtain yeast for subsequent fermentations, carbon dioxide recovery	2—7 d	12–22 (ale) 4–15 (lager)
Maturation and conditioning	Beer storage in oxygen free tank, beer cooling, adding processing aids	Beer maturation, adjustment of the taste, adjustment of CO_2 content, sedimentation of yeast and cold trub, beer stabilization	7–21 h	−1–0
Beer clarification	Centrifugation, filtration	Removal of yeast and cold trub	1–2 h	−1–0
Biological stabilization	Pasteurization of sterile filtration	Killing or removing of microorganisms	1–2 h	62–72 (past.) −1–0 (filtr.)
Packaging	Filling of bottles, cans, casks, and kegs; pasteurization of small volumes in packings	Production of packaged beer according to specifications	0.5–1.5 h	−1–room temperature

dextrin material (Table 33.2). The fermentable sugars typically make up 70–80% of the total carbohydrate (MacWilliam 1968). The three major fermentable sugars are glucose, α-glucosides maltose, and maltotriose. Maltose is by far the most abundant of these sugars, typically accounting for 50–70% of the total fermentable sugars in an all-malt wort. Sucrose and fructose are present in a low concentration. The unfermentable dextrins play little part in brewing. Wort fermentability may be reduced or increased by using solid (e.g., corn grits, flakes, or rice) or liquid adjuncts (e.g., sugar syrups).

Table 33.2. Carbohydrate Composition of Worts

Origin Type of Wort	Danish Lager 11°P	Canadian Lager 13°P	British Pale Ale 10°P	Canadian Corn Adjunct Wort	All-Malt Wort 18°P
Fructose (g/L) (%)[a]	2.1	1.5	3.3	1.3	3.0
	2.7	1.6	4.8	1.3	
Glucose (g/L) (%)[a]	9.1	10.3	10.0	14.7	13.0
	11.6	10.9	14.5	15.7	
Sucrose (g/L) (%)[a]	2.3	4.2	5.3	1.8	
	2.9	4.5	7.7	1.9	
Maltose (g/L) (%)[a]	52.4	60.4	38.9	62.8	80.0
	66.6	64.2	56.5	67.0	
Maltotriose (g/L) (%)[a]	12.8	17.7	11.4	13.2	24.0
	16.3	18.8	16.5	14.1	
Total ferm. sugars (g/L)	78.7	94.1	68.9	93.8	121.0
Maltotetraose (g/L)	2.6	7.2	2.0		
Higher sugars (g/L)	21.3	26.8	25.2		
Total dextrins (g/L)	23.9	34.0	25.2		
Total sugars (g/L)	102.6	128.1	94.1	117.5	

Source: Patel and Ingledew (1973), Huuskonen et al. (2010), and Hough et al. (1982).
[a]Percent of the total fermentable sugars.

Brewing strains consume the wort sugars in a specific sequence: glucose is consumed first, followed by fructose, maltose, and finally maltotriose. The uptake and consumption of maltose and maltotriose is repressed or inactivated at elevated glucose concentrations. Only when 60% of the wort glucose has been taken up by the yeast, the uptake and consumption of maltose will start. Maltotriose uptake is inhibited by high glucose and maltose concentrations. When high amounts of carbohydrate adjuncts (e.g., glucose) or high-gravity wort are employed, the glucose repression is even more pronounced, resulting in fermentation delays (Stewart and Russell 1993).

The efficiency of brewer's yeast strains to effect alcoholic fermentation is dependent upon their ability to utilize the sugars present in wort. This ability very largely determines the fermentation rate as well as the final quality of the beer produced. In order to optimize the fermentation efficiency of the primary fermentation, a detailed knowledge of the sugar consumption kinetics, which is linked to the yeast growth kinetics, is required (Willaert 2001).

MALTOSE AND MALTOTRIOSE METABOLISM

The yeast *Saccharomyces cerevisiae* transports the monosaccharides across the cell membrane by the hexose transporters. There are 20 genes encoding hexose transporters (Dickinson 1999, Rintala et al. 2008): 18 genes encoding transporters (*HXT1* to *HXT17*, *GAL2*) and two genes encoding (*SNF3*, *RGT2*). The disaccharide maltose and the trisaccharide maltotriose are transported by specific transporters into the cytoplasm, where these molecules are hydrolyzed by the same α-glucosidase yielding two or three molecules of glucose, respectively (Panchal and Stewart 1979, Zheng et al. 1994a).

Maltose utilization in yeast is conferred by any one of five *MAL* loci: *MAL1* to *MAL4* and *MAL6* (Bisson et al. 1993, Dickinson 1999). Each locus consists of three genes (*MALx1*, where x stands for one of the five loci): gene 1 encodes a maltose transporter (permease), gene 2 encodes a maltase (α-glucosidase), and gene 3 encodes a transcriptional activator of the other two genes. Thus, for example, the maltose transporter gene at the *MAL1* locus is designated *MAL61*. The three genes of a *MAL* locus are all required to allow fermentation. Alternatively, some authors use gene designations such as for the *MAL1* locus: *MAL1T* (transporter = permease), *MAL1R* (regulator), and *MAL1S* (maltase). The genetic and biochemical analysis of maltose fermentation by yeast cells revealed a series of five unlinked telomere-associated multigene *MAL* loci: *MAL1* (chromosome VII), *MAL2* (chromosome III), *MAL4* (chromosome II), and *MAL6* (chromosome VIII). The *MAL* loci exhibit a very high degree of homology and are telomere linked, suggesting that they evolved by translocation from telomeric regions of different chromosomes (Michels et al. 1992). Since a fully functional or partial allele of the *MAL1* locus is found in all strains of *S. cerevisiae*, this locus is proposed as the progenitor of the other *MAL* loci (Chow et al. 1983), as all *S. cerevisiae* strains, and even its closest related yeast species *S. paradoxus*, contain *MAL1* sequences near the right telomere of chromosome VII. The genes in the *MAL* loci show a high degree of sequence and functional similarity, but there can be extensive variability, and several different alleles that determine distinct phenotypes (i.e., *MAL*-inducible and *MAL*-constitutive strains) have been described (Novak et al. 2004). Gene dosage studies performed with laboratory strains of yeast have shown that the transport of maltose in the cell may be the rate-limiting step in the utilization of this sugar (Goldenthal et al. 1987). Constitutive expression

of the maltose transporter gene (*MALT*) with high-copy-number plasmids in a lager yeast strain has been found to accelerate the fermentation of maltose during high-gravity (24°P) brewing (Kodama et al. 1995). The constitutive expression of *MALS* and *MALR* had no effect on maltose fermentability.

The control over *MAL* gene expression is exerted at three levels. The presence of maltose induces, whereas glucose represses, the transcription of *MALS* and *MALT* genes (Federoff et al. 1983a, 1983b, Needleman et al. 1984). The constitutively expressed regulatory protein (*MALR*) binds near the *MALS* and *MALT* promotors and mediates the induction of *MALS* and *MALT* transcription (Cohen et al. 1984, Chang et al. 1988, Ni and Needleman 1990). Experiments with *MALR*-disrupted strains led to the conclusion that MalRp is involved in glucose repression (Goldenthal and Vanoni 1990, Yao et al. 1994). Relatively little attention has been paid to posttranscriptional control, that is, the control of translational efficiency, or mRNA turnover, as mechanisms complementing glucose repression (Soler et al. 1987). The addition of glucose to induced cells has been reported to cause a 70% increase in the liability of an mRNA population containing a fragment of *MALS* (Federoff et al. 1983a). The third level of control is posttranslational modification. In the presence of glucose, maltose permease is either reversibly converted to a conformational variant with decreased affinity (Siro and Lövgren 1979, Peinado and Loureiro-Dias 1986) or irreversibly proteolytically degraded depending on the physiological conditions (Lucero et al. 1993, Riballo et al. 1995). The latter phenomenon is called catabolite inactivation. Glucose repression is accomplished by the Mig1p repressor protein, which is encoded by the *MIG1* gene (Nehlin and Ronne 1990). It has been shown that Mig1p represses the transcription of all three *MAL* genes by binding upstream of them (Hu et al. 1995). The *MIG1* gene has been disrupted in a haploid laboratory strain and in an industrial polyploid strain of *S. cerevisiae* (Klein et al. 1996). In the *MIG1*-disrupted haploid strain, glucose repression was partly alleviated; that is, maltose metabolism was initiated at higher glucose concentrations than in the corresponding wild-type strain. In contrast, the polyploid Δ*mig1* strain exhibited an even more stringent glucose control of maltose metabolism than the corresponding wild-type strain, which could be explained by a more rigid catabolite inactivation of maltose permease, affecting the uptake of maltose.

All α-glucoside transport systems so far characterized in yeast are H^+-transporters that use the electrochemical proton gradient to actively transport these sugars into the cell (Crumplen et al. 1996, Stambuk and de Araujo 2001). It has been shown that maltose uptake is the rate-limiting step of fermentation (Kodama et al. 1995, Wang et al. 2002, Rautio and Londesborough 2003). At least three different maltose transporters have been identified in *S. cerevisiae*, and while the *MALx1* transporters (and probably the two *MPH2* and *MPH3* alleles) encode high affinity ($K_m = 2$–4 mmol l^{-1}) maltose permeases, the *AGT1* permease (a gene present in partially functional *mal1g* loci) transports maltose with lower ($K_m \approx 20$ mmol l^{-1}) affinity (Han et al. 1995, Stambuk and de Araujo 2001, Day et al. 2002a, Alves et al. 2007, 2008). *AGT1* is found in many *S. cerevisiae* laboratory strains and maps to a naturally occurring, partially functional

allele of the *MAL1* locus (Han et al. 1995). Agt1p is a highly hydrophobic, postulated integral membrane protein. It is 57% identical to Mal61p (the maltose permease encoded at *MAL6*) and is also a member of the 12 transmembrane domain superfamily of sugar transporters (Nelissen et al. 1995). Like Mal61p, Agt1p is a high-affinity, maltose/proton symporter, but Mal61p is capable of transporting only maltose and turanose, while Agt1p transports these two α-glucosides as well as several others including isomaltose, α-methylglucoside, maltotriose, palatinose, trehalose and melezitose. *AGT1* expression is maltose inducible and induction is mediated by the Mal-activator.

Brewing strains of yeast are polyploid, aneuploid, or, in the case of lager strains, alloploid. Recently, Jespersen et al. (1999) examined 30 brewing strains of yeast (5 ale strains and 25 lager strains) with the aim of examining the alleles of maltose and maltotriose transporter genes contained by them. All the strains of brewer's yeast examined, except two, were found to contain *MAL11* and *MAL31* sequences, and only one of these strains lacked *MAL41*. *MAL21* was not present in the 5 ale strains and 12 of the lager strains. *MAL61* was not found in any of the yeast chromosomes other than those known to carry *MAL* loci. Sequences corresponding to the *AGT1* gene (transport of maltose and maltotriose) were detected in all but one of the yeast strains.

Although maltose is easily fermented by the majority of yeast strains after glucose exhaustion, maltotriose is not only the least preferred sugar for uptake by these *Saccharomyces* cells, but many yeasts may not use this α-glucosidase at all (Zheng et al. 1994a, Yoon et al. 2003). Incomplete maltotriose uptake during brewing fermentations results in yeast fermentable extract in beer, material loss, greater potential for microbiological stability and sometimes atypical beer flavor profiles (Stewart and Russell 1993). Maltotriose uptake from wort is always slower with ale strains than with lager strains under similar fermentation conditions. However, the initial transport rates are similar to those of maltose in a number of ale and lager strains. Elevated osmotic pressure inhibits the transport and uptake of glucose, maltose and maltotriose with maltose and maltotriose being more sensitive to osmotic pressure than glucose in both lager and ale strains. Ethanol (5% w/v) stimulated the transport of maltose and maltotriose, due in all probability to an ethanol-induced change in the plasma membrane configuration, but had no effect on glucose transport. Higher ethanol concentrations inhibited the transport of all three sugars.

Maltotriose uptake shows complex kinetics indicating the presence of high- and low-affinity transport activities, and studies on sugar utilization revealed that maltose and maltotriose are apparently transported by different permeases (Zheng et al. 1994b, Zastrow et al. 2001). Two genes are recognized as permease genes for transporting maltotriose in yeasts: *AGT1* transporter from *S. cerevisiae* and *MTY1* (also called *MTT1*) permease from *S. pastorianus*. They are characterized as low-affinity ($K_m \approx 20$ mmol l^{-1}) maltotriose transporters (Stambuk and de Araujo 2001, Dietvorst et al. 2005, Salema-Oom et al. 2005, Alves et al. 2007, 2008).

Recent reports regarding the observed patterns of maltose and maltotriose utilization by yeast cells show contradicting results.

Data indicated that all known α-glucoside transporters present in *S. cerevisiae*, including the maltose permeases *MAL31*, *MAL61*, *MPH2*, and *MHP3*, allowed growth of the yeast cells on both maltose and maltotriose (Day et al. 2002a, 2002b). Their kinetic analysis of maltose and maltotriose uptake indicated that all these transporters, including *AGT1* permease, could transport both sugars with practically the same affinities and capacity. Recently, to better understand maltotriose utilization by yeast strains, an analysis of maltotriose and maltotriose utilization by 52 laboratory and industrial *Saccharomyces* yeast strains was performed (Duval et al. 2009). Microarray comparative genome hybridization (aCGH) was used to correlate the observed phenotypes with copy number variations in genes known to be involved in maltose and maltotriose utilization by yeasts. The results showed that *S. pastorianus* strains utilized maltotriose more efficiently than *S. cerevisiae* strains and highlighted the importance of the *AGT1* gene for efficient maltotriose utilization by *S. cerevisiae* yeasts. The fermentation performance of a lager (*S. pastorianus*) strain was improved when its *AGT1* gene was replaced with the *AGT1* gene of an ale (*S. cerevisiae*) strain, since the *ATG1* gene of the lager strains studied contained a premature stop codon and did not encode functional transporters (Vidgren et al. 2005, 2009). The transformants with repaired *AGT1* had higher maltose transport activity, especially after growth on glucose, which represses endogeneous α-glucoside transporter genes. The sequences of two *AGT1*-encoded α-glucosidase transporters with different efficiencies of maltotriose transport in two *Saccharomyces* strains were compared (Smit et al. 2008). The amino acids Thr[505] and Ser[557], which are respectively located in the transmembrane (TM) segment TM[11] and on the intracellular segment after TM[12] of the *AGT1*-encoded α-glucosidase transporters, are critical for efficient transport of maltotriose in *S. cerevisiae*. It was also shown that maltotriose utilization could be improved by attaching a maltase encoded by *MAL32* to the yeast cell surface (Dietvorst et al. 2007).

Glycogen and Trehalose Metabolism

Glycogen and trehalose are the main storage carbohydrates in yeast cells (Panek 1991). The synthesis of both compounds commences with the formation of uridine diphosphate (UDP)-glucose catalyzed by UDP-glucose pyrophosphorylase.

Glycogen is a reserve carbohydrate that is metabolized during periods of starvation. It is a branched polysaccharide composed of linear α-(1,4)-glycosyl chains with α-(1,6)-linkages (similar to starch but with a higher degree of branching). It is synthesized starting from glucose via glucose-6-phosphate and glucose-1-phosphate. Glycogen is synthesized from glucose, via glucose-6-phosphate and glucose-1-phosphate (François and Parrou 2001). UDP serves as a carrier of glucose units and is formed by a two-step reaction, catalyzed by phosphoglucomutase and UDP-glucose phosphorylase. Glycogen synthesis is initiated by glycogenin that produces a short α-(1,4)-glucosyl chain, which is elongated by glycogen synthase. The α-(1,6)-glucosidic bonds are formed by the branching enzyme Glc3. The dissimilation of glycogen occurs through the action of glycogen phosphory-

lase, which releases glucose-1-phosphate from the nonreducing ends of the glycogen chains, and the debranching enzyme Gdb1, which transfers a maltosyl unit to the end of an adjacent linear α-(1,4) chain and releases glucose by cleaving the remaining α-(1,6)-linkage.

When yeast cells are pitched in aerated wort, an immediate glycogen mobilization is observed (Quain 1988, Boulton 2000). Glycogen accumulates during the exponential growth phase, after oxygen has been consumed. When the yeast growth is ceased toward the end of the primary fermentation, are maximum glycogen levels obtained. In the stationary phase, the glycogen levels decline slowly. Glycogen provides energy for the synthesis of sterols and unsaturated fatty acids during the aerobic phase of the beer fermentation, and energy for the cellular maintanance functions during the stationary phase in the storage phase between cropping and pitching (Quain and Tubb 1982, Boulton et al. 1991). The glycogen content is directly related to subsequent fermentation performance. Therefore, yeast storage occurs best at a low temperature, without agitation and under an atmosphere of nitrogen or carbon dioxide to minimize glycogen breakdown (Murray et al. 1984).

The regulation of the glycogen content is complex and occurs in part by the cAMP/PKA pathway (Smith et al. 1998). Glycogen accumulation is repressed by a high PKA-activity (François and Parrou 2001). The glycogen content increases and the PKA-activity is reduced, when an essential nutrient is progressively consumed from the growth medium.

Trehalose is a disaccharide (α-D-glucopyranosyl-1,1- α-D-glucopyranoside) which contains two molecules of D-glucose (Boulton and Quain 2006). Trehalose biosynthesis is catalyzed by the trehalose synthase complex, which forms trehalose-6-phosphate from UDP-glucose and glucose-6-phosphate, and next dephosphorylates it to trehalose. Trehalose is degradaded by the neutral (Nth1) or the acid (Ath1) trehalase (Panek and Panek 1990, François and Parrou 2001). Like glycogen, trehalose also accumulates in yeast under conditions of nutrient limitation. It has been observed that trehalose rapidly accumulates in response to environmental stress, such as dehydration, heating and osmotic stress (during high gravity brewing) (Majara et al. 1996, Hounsa et al. 1998). Under stress conditions, the higher levels of trehalose protect the cells by binding to membranes and proteins (François and Parrou 2001). Trehalose accumulation in response to stress is, however, a transient phenomenon (Parrou et al. 1997).

In the beginning of the primary fermentation, high glucose levels activate the camp/PKA pathway (Zähringer et al. 2000). This results in posttranslational activation of neutral trehalase and in induction of its *NTH1* gene, and in repression of the trehalose synthase genes, which results in reduced levels of trehalose.

Wort Fermentation

Before the fermentation process starts, wort is aerated. This is a necessary step since oxygen is required for the synthesis of sterols and unsaturated fatty acids, which are incorporated in the yeast cell membrane (Rogers and Stewart 1973). It has been

shown that ergosterol and unsaturated fatty acids increase both in concentration as long as oxygen is present in the wort (e.g., Haukeli and Lie 1979). A maximum concentration is obtained in 5–6 hours after pitching, but the formation rate is dependent upon the pitching rate and the temperature. Unsaturated fatty acids can also be taken up from the wort, but all malt wort does not contain sufficient unsaturated lipids to support a normal growth rate of yeast. Adding lipids to the wort, especially unsaturated fatty acids might be an interesting alternative (Moonjai et al. 2000a, 2000b).

The oxygen required for lipid biosynthesis can also be introduced by oxygenation of the separated yeast cells. The use of the preoxygenation technique resulted in more controllable and consistent fermentations, and as a consequence, in a more balanced beer flavor profile (Jakobsen 1982, Ohno and Takahashi 1986a, 1986b, Boulton et al. 1991, Devuyst et al. 1991, Masschelein et al. 1995, Depraetere et al. 2003, Depraetere 2007). Recently, the impact of yeast preoxygenation on yeast metabolism has been assessed (Verbelen et al. 2009). Therefore, expression analysis was performed of genes that are of importance in oxygen-dependent pathways, oxidative stress response and general stress response during 8 hours of preoxygenation. The gene expressions of both the important transcription factors Hap1 and Rox1, involved in oxygen sensing, were mainly increased in the first 3 hours, while *YAP1* expression, which is involved in the oxidative stress response, increased drastically only in the first 45 minutes. The results also show that stress-responsive genes (*HSP12*, *SSA3*, *PAU5*, *SOD1*, *SOD2*, *CTA1*, and *CTT1*) were induced during the process, together with the accumulation of trehalose. The accumulation of ergosterol and unsaturated fatty acids was accompanied by the expression of *ERG1*, *ERG11*, and *OLE1*. Genes involved in respiration (*QCR9*, *COX15*, *CYC1*, and *CYC7*) also increased during preoxygenation. Yeast viability did not decrease during the process, and the fermentation performance of the yeast reached a maximum after 5 hours of preoxygenation. These results suggest that yeast cells acquire a stress response along the preoxygenation period, which makes them more resistant against the stressful conditions of the preoxygenation process and the subsequent fermentation.

Different devices are used to aerate the cold wort: ceramic or sintered metal candles, aeration plants employing venturi pipes, two component jets, static mixers, or centrifugal mixers (Kunze 1999). The principle of these devices is that very small air (oxygen) bubbles are produced and quickly dissolve during turbulent mixing.

As a result of this aeration step, carbohydrates are degraded aerobically during the first few hours of the "fermentation" process. The aerobic carbohydrate catabolism takes typically 12 hours for a lager fermentation.

During the first hours of the fermentation process, oxidative degradation of carbohydrates occurs through the glycolysis and Krebs (TCA) cycle. The energy efficiency of glucose oxidation is derived from the large number of $NADH_2^+$ produced for each mole of glucose oxidized to CO_2. The actual wort fermentation gives alcohol and carbon dioxide via the Embden-Meyerhof-Parnas (glycolytic) pathway. The reductive pathway from pyruvate to ethanol is important since it regenerates NAD^+. Energy is obtained solely from ATP-producing steps of the Embden-Meyerhof-Parnas pathway. During fermentation, the activity of the TCA cycle is greatly reduced, although it still serves as a source of intermediates for biosynthesis (Lievense and Lim 1982).

Lagunas (1979) observed that during aerobic growth of *S. cerevisiae*, respiration accounts for less than 10% of glucose catabolism, the remainder being fermented. Increasing sugar concentrations resulting in a decreased oxidative metabolism is known as the Crabtree effect. This was traditionally explained as an inhibition of the oxidative system by high concentrations of glucose. Nowadays, it is generally accepted that the formation of ethanol at aerobic conditions is a consequence of a bottleneck in the oxidation of pyruvate, for example, in the respiratory system (Petrik et al. 1983, Rieger et al. 1983, Käppeli et al. 1985, Fraleigh et al. 1989, Alexander and Jeffries 1990).

A reduction of ethanol production can be achieved by metabolic engineering of the carbon flux in yeast resulting in an increased formation of other fermentation product. A shift of the carbon flux towards glycerol at the expense of ethanol formation in yeast was achieved by simply increasing the level of glycerol-3-phosphate dehydrogenase (Michnick et al. 1997, Nevoigt and Stahl 1997, Remize et al. 1999, Dequin 2001). The *GDP1* gene, which encodes glycerol-3-phosphate dehydrogenase, has been overexpressed in an industrial lager brewing yeast to reduce the ethanol content in beer (Nevoigt et al. 2002). The amount of glycerol produced by the *GDP1*-overexpressing yeast in fermentation experiments—simulating brewing conditions—was increased 5.6 times and ethanol was decreased by 18% compared to the wild-type strain. Overexpression did not affect the consumption of wort sugars and only minor changes in the concentration of higher alcohols, esters and fatty acids could be observed. However, the concentrations of several other by-products, particularly acetoin, diacetyl, and acetaldehyde, were considerably increased.

Mutants of *S. cerevisiae* strains deficient in tricarboxylic acid cycle genes have been reported as suitable strains for the production of nonalcoholic beer (Navratil et al. 2002). Strains deficient in fumarase and α-ketoglutarate dehydrogenase made nonalcoholic beers with an alcohol content lower than 0.5% (v/v) (Selecky et al. 2008). The low ethanol content was compensated by the considerable increase of organic acids (citrate, succinate, fumarate, and malate). Some of the mutants released high levels of lactic acid, which protects beers against contamination and masks an unacceptable worty off-flavor.

METABOLISM OF BIOFLAVORING BY-PRODUCTS

Yeast is an important contributor to flavor development in fermented beverages. The compounds, which are produced during fermentation, are many and varied, depending on both the raw materials and the microorganisms used. The interrelation between yeast metabolism and the production of bioflavoring by-products is illustrated in Figure 33.2. The important flavor compounds produced by yeast can be classified into five categories: alcohols, esters, organic acids, carbonyl compounds

into aliphatic (*n*-propanol, isobutanol, 2-methylbutanol (or active amyl alcohol), and 3-methylbutanol (or isoamyl alcohol)), and aromatic (2-phenylethanol, tyrosol, tryptophol) higher alcohols. Aliphatic higher alcohols contribute to the "alcoholic" or "solvent" aroma of beer, and produce a warm mouthfeel. The aromatic alcohol 2-phenylethanol has a sweet rose-like aroma and has a positive contribution to the beer aroma. It is believed that this compound masks the dimethyl sulfide (DMS) perception (Hegarty et al. 1995). The aroma of tyrosol and tryptophol are undesirable, but they are only present above their thresholds in some top-fermented beers.

Higher alcohols are synthesized by yeast during fermentation via the catabolic (Ehrlich) and anabolic pathway (amino acid metabolism) (Ehrlich 1904, Chen 1978, Oshita et al. 1995, Hazelwood et al. 2008). In the catabolic pathway, the yeast uses the amino acids of the wort to produce the corresponding α-keto acid via a transamination reaction. Isoamyl alcohol, isobutanol, and phenylethanol are produced via this route from leucine, valine, and phenylalanine, respectively. An outsider in this pathway is propanol, which is derived from threonine via an oxidative deamination. The excess oxoacids are subsequently decarboxylated into aldehydes and further reduced (alcohol dehydrogenase) to higher alcohols. This last reduction step also regenerates NAD^+.

Dickinson and coworkers looked at the genes and enzymes, which are used by *S. cerevisiae* in the catabolism of leucine to isoamyl alcohol (Dickinson et al. 1997), valine to isobutanol (Dickinson et al. 1998), and isoleucine to active amyl alcohol (Dickinson et al. 2000). In all cases, the general sequence of biochemical reactions is similar, but the details for the formation of the individual alcohols are surprisingly different. The branched-chain amino acids are first deaminated to the corresponding α-ketoacids (α-ketoisocapric acid from leucine, α-ketoisovaleric acid from valine, and α-keto-β-methylvaleric

Figure 33.2. Interrelation between yeast metabolism and the production of bioflavoring by-products.

(aldehydes and vicinal diketones), and sulfur-containing compounds (Hammond 1993). In addition, some speciality beers can contain important concentrations of volatile phenol compounds (Vanbeneden et al. 2007).

BIOSYNTHESIS OF HIGHER ALCOHOLS

During beer fermentation, higher alcohols (also called "fusel alcohols") are produced by yeast cells as by-products and represent the major fraction of the volatile compounds. More than 35 higher alcohols in beer have been described. Table 33.3 gives the most important compounds, which can be classified

Table 33.3. Major Higher Alcohols in Beer (Partly Adapted From NN 2000.)

Compound	Flavor Threshold (mg/L)	Aroma or Taste[b]	Concentration Range (mg/L) Bottom Fermentation	Concentration Range (mg/L) Top Fermentation
n-Propanol	600[c], 800[b]	Alcohol	7–19 (12)[a],[f], 6–30[j]	20–45[i]
Isobutanol	100[c], 80–100[g], 200[b]	Alcohol	4–20 (12)[f], 6–32[j]	10–24[i]
2-Methylbutanol	50[c], 50–60[g], 70[b]	Alcohol	9–25 (15)[a], 12–16[j]	80–140[i]
3-Methylbutanol	50[c], 50–60[g], 65[b]	Fusely, pungent	25–75 (46)[a], 30–60[j]	80–140[i]
2-Phenylethanol	5[a], 40[c], 45–50[g], 75[d], 125[b]	Roses, sweetish	11–51 (28)[f], 4–22[g], 16–42[h], 4–10[j]	35–50[g], 8–25[a], 18–45[i]
Tyrosol	10[a], 10–20[e], 20[c], 100[d], [g], 200[b]	Bitter chemical	6–9[a], 6–15[a]	8–12[g], 7–22[g]
Tryptophol	10[a], 10–20[e], 200[d]	Almonds, solvent	0.5–14[a]	2–12[g]

acid from leucine). There are significant differences in the way each α-ketoacid is subsequently decarboxylated. The catabolism of phenylalanine to 2-phenylethanol and of tryptophan were also studied (Dickinson et al. 2003). Phenylalanine and tryptophan are first deaminated to 3-phenylpyruvate and 3-indolepyruvate, respectively, and then decarboxylated. These studies revealed that all amino acid catabolic pathways studied to date use a subtle different spectrum of decarboxylases from the five-membered family that comprises Pdc1p, Pdc5p, Pdc6p, Ydl080cp, and Ydr380wp. Using strains containing all possible combinations of mutations affecting the seven *AAD* genes (putative aryl alcohol dehydrogenases), five *ADH* and *SFA1* (other alcohol dehydrogenase genes), showed that the final step of amino acid catabolism can be accomplished by any one of the ethanol dehydrogenases (Ahd1p, Ahd2p, Ahd3p, Ahd4p, Ahd5p) or Sfa1p (formaldehyde dehydrogenase).

In the anabolic pathway, the higher alcohols are synthesized from α-keto acids during the synthesis of amino acids from the carbohydrate source. The pathway choice depends on the individual higher alcohol and on the level of available amino acids available. The importance of the anabolic pathway decreases as the number of carbon atoms in the alcohol increases (Chen 1978) and increases in the later stage of fermentation as wort amino acids are depleted (MacDonald et al. 1984). Yeast strain, fermentation conditions, and wort composition all have significant effects on the combination and levels of higher alcohols that are formed (MacDonald et al. 1984).

Conditions that promote yeast cell growth such as high levels of nutrients (amino acids, oxygen, lipids, zinc, ...) and increased temperature and agitation stimulate the production of higher alcohols (Engan 1969, Engan and Aubert 1977, Landaud et al. 2001, Boswell et al. 2002). The synthesis of aromatic alcohols is especially sensitive to temperature changes. On the other hand, conditions that restrict yeast growth, such as lower temperature and higher pressure, reduce the extent of higher alcohol production. Higher pressures can reduce the extent of cell growth and, therefore, the production of higher alcohols (Landaud et al. 2001). The yeast strain, fermentation conditions, and wort composition have all significant effects on the pattern and concentrations of synthesized higher alcohols. Supplemen-

tation of wort with valine, isoleucine, and leucine induces the formation of isobutanol, amyl alcohol, and isoamyl alcohol, respectively (Äyräpää 1971, Kodama et al. 2001). The overexpression of the branched chain amino acid transferases genes *BAT1* and *BAT2* result in an increased production of isoamyl alcohol and isobutanol (Lilly et al. 2006).

BIOSYNTHESIS OF ESTERS

Esters are very important flavor compounds in beer. They have an effect on the fruity/flowery aromas. Table 33.4 shows the most important esters with their threshold values, which are considerably lower than those for higher alcohols. The major esters can be subdivided into acetate esters and C_6–C_{10} medium-chain fatty acid ethyl esters. They are desirable components of beer when present in appropriate quantities and proportions but can become unpleasant when in excess.

Esters are produced by yeast both during the growth phase (60%) and also during the stationary phase (40%) (NN 2000). They are formed by the intracellular reaction between a fatty acyl-coenzyme A and an alcohol:

$$R'OH + RCO - ScoA \rightarrow RCOOR' + CoASH \qquad (1)$$

This reaction is catalyzed by alcohol acyltransferases (AATases; or ester synthethases) of the yeast. Since acetyl CoA is also a central molecule in the synthesis of lipids and sterols, ester synthesis is linked to the fatty acid metabolism (see also Fig. 33.2). The majority of acetyl-CoA is formed by oxidative decarboxylation of pyruvate, while most of the other acyl-CoAs are derived from the acylation of free CoA, catalyzed by acyl-CoA synthase.

Several enzymes are involved in the synthesis, the best characterized are AATase I and II that are encoded by *ATF1* and *ATF2*. Alcohol acetyltransferase (AAT) has been localized in the plasma membrane (Malcorps and Dufour 1987) and found to be strongly inhibited by unsaturated fatty acids, ergosterol, heavy metal ions, and sulfydryl reagents (Minetoki et al. 1993). Subcellular fractionation studies conducted during the batch fermentation cycle demonstrated the existence of both cytosolic and membrane-bound AAT (Ramos-Jeunehomme et al. 1989, Ramos-Jeunehomme et al. 1991). In terms of controlling

Table 33.4. Major Esters in Beer (Adapted From Dufour and Malcorps 1994.)

Compound	Flavor Threshold (mg/L)	Aroma	Concentration Range (mg/L) in 48 Lagers
Ethyl actetate	20–30, 30[a]	Fruity, solvent-like	8–32 (18.4)[a], 5–40[b]
Isoamyl acetate	0.6–1.2, 1.2[a]	Banana, peardrop	0.3–3.8 (1.72), <0.01–2.8[b]
Ethyl caproate (ethyl hexanoate)	0.17–0.21, O.21[a]	Apple-like with note of aniseed	0.05–0.3 (0.14), 0.01–0.54[b]
Ethyl caprylate (ethyl octanoate)	0.3–0.9, 0.9[a]	Apple-like	0.04–0.53 (0.17), 0.01–1.2[b]
2-Phenylethyl acetate	3.8[a]	Roses, honey, apple, sweetish	0.10–0.73 (0.54)

[a]Mean value.

ester formation on a metabolic basis, it has further been shown that ester synthesizing activity of AAT is dependent on its positioning within the yeast cell. An interesting feature of this distribution pattern is that specific rates of acetate ester formation varied directly with the level of cytosolic AAT activity (Masschelein 1997).

The *ATF1* gene, which encodes AAT, has been cloned from *S. cerevisiae* and brewery lager yeast (*S. cerevisiae uvarum*) (Fujii et al. 1994). An hydrophobicity analysis suggested that AAT does not have a membrane-spanning region that is significantly hydrophobic, which contradicts the membrane-bound assumption. A Southern analysis of the yeast genomes in which the *ATF1* gene was used as a probe revealed that *S. cerevisiae* has one *ATF1* gene, while brewery lager yeast has one *ATF1* gene and another homologous gene (*Lg-ATF1*). The AAT activities have been compared in vivo and in vitro under different fermentation conditions (Malcorps et al. 1991). This study suggested that ester synthesis is modulated by a repression–induction of enzyme synthesis or processing the regulation of which is presumably linked to lipid metabolism. Other enzymes are Eht1 (ethanolhexanoyl transferase) and Eeb1, which are responsible for the formation of ethyl esters (Verstrepen et al. 2003, Saerens et al. 2006).

The ester production can be altered by changing the synthesis rate of certain fusel alcohols. Hirata et al. (1992) increased the isoamyl acetate levels by introducing extra copies of the *LEU4* gene in the *S. cerevisiae* genome. A comparable *S. cerevisiae uvarum* mutant has been isolated (Lee et al. 1995). The mutants have an altered regulation pattern of amino acid metabolism and produce more isoamyl acetate and phenylethyl acetate.

Isoamyl acetate is synthesized from isoamyl alcohol and acetyl coenzyme A by AAT and is hydrolyzed by esterases at the same time in *S. cerevisiae*. To study the effect of balancing both enzyme activities, yeast strains with different numbers of copies of *ATF1* gene and isoamyl acetate-hydrolyzing esterase gene (*IAH1*) have been constructed and used in small-scale sake brewing (Fukuda et al. 1998). Fermentation profiles as well as components of the resulting sake were largely alike. However, the amount of isoamyl acetate in the sake increased with increasing ratio of AAT/Iah1p esterase activity. Therefore, it was concluded that the balance of these two enzyme activities is important for isoamyl acetate accumulation in sake mash.

The synthesis of acetate esters by *S. cerevisiae* during fermentation is ascribed to at least three acetyltransferase activities, namely, AAT, ethanol acetyltransferase, and isoamyl AAT (Lilly et al. 2000). To investigate the effect of increased AAT activity on the sensory quality of Chenin blanc wines and distillates from Colombar base wines, the *ATF1* gene of *S. cerevisiae* was overexpressed. Northern blot analysis indicated constitutive expression of *ATF1* at high levels in these transformants. The levels of ethyl acetate, isoamyl acetate and 2-phenylethyl acetate increased 3- to 10-fold, 3.8- to 12-fold, and 2- to 10-fold, respectively, depending on the fermentation temperature, cultivar, and yeast used. The concentrations of ethyl caprate, ethyl caprylate, and hexyl acetate only showed minor changes, whereas the acetic acid concentration decreased by more than half. This study established the concept that the overexpression

of acetyltransferase genes such as *ATF1* could profoundly affect the flavor profiles of wines and distillates deficient in aroma.

In order to investigate and compare the roles of the known *S. cerevisiae* AATs, Atf1p, Atf2p, and Lg-Atf1p, in volatile ester production, the respective genes were either deleted or overexpressed in a laboratory strain and a commercial brewing strain (Verstrepen et al. 2003). Analysis of the fermentation products confirmed that the expression levels of *ATF1* and *ATF2* greatly affect the production of ethyl acetate and isoamyl acetate. GC-MS analysis revealed that Atf1p and Atf2p are also responsible for the formation of a broad range of less volatile esters, such as propyl acetate, isobutyl acetate, pentyl acetate, hexyl acetate, heptyl acetate, octyl acetate, and phenyl ethyl acetate. With respect to the esters analyzed in this study, Atf2p seemed to play only a minor role compared to Atf1p. The *atf1Δatf2Δ* double deletion strain did not form any isoamyl acetate, showing that together, Atf1p and Atf2p are responsible for the total cellular isoamyl AAT activity. However, the double deletion strain still produced considerable amounts of certain other esters, such as ethyl acetate (50% of the wild-type strain), propyl acetate (50%), and isobutyl acetate (40%), which provides evidence for the existence of additional, as-yet-unknown ester synthases in the yeast proteome. Interestingly, overexpression of different alleles of *ATF1* and *ATF2* led to different ester production rates, indicating that differences in the aroma profiles of yeast strains may be partially due to mutations in their *ATF* genes.

Recently, it has been discovered that the Atf1 enzyme is localized inside lipid vesicles in the cytoplasm of the yeast cell (Verstrepen 2003). Lipid vesicles are small organelles in which certain neutral lipids are metabolized or stored. This indicates that fruity esters are possibly by-products of these processes.

Ester formation is highly dependent on the yeast strain used (Nykänen and Nykänen 1977, Peddie 1990, Verstrepen et al. 2003b) and on certain fermentation parameters such as temperature (Engan and Aubert 1977, Gee and Ramirez 1994, Sablayrolles and Ball 1995), specific growth rate (Gee and Ramirez 1994), pitching rate (Maule 1967, D'Amore et al. 1991, Gee and Ramirez 1994), and top pressure (NN 2000, Verstrepen et al. 2003b). Additionally, the concentrations of assimilable nitrogen compounds (Hammond 1993, Calderbank and Hammond 1994, Sablayrolles and Ball 1995), carbon sources (Pfisterer and Stewart 1975, White and Portno 1979, Younis and Stewart 1998, 2000), dissolved oxygen (Anderson and Kirsop 1975a, 1975b, Avhenainen and Mäkinen 1989, Sablayrolles and Ball 1995), and fatty acids (Thurston et al. 1981, 1982) can influence the ester production rate.

Acetate ester formation in brewer's yeast is controlled mainly by the expression level of the AATase-encoding genes (Verstrepen et al. 2003b). Additionally, changes in the availability of the two substrates for ester production, higher alcohols and acyl-CoA, also influences ester synthesis rates. Any factor that influences the expression of the ester synthase genes and/or the concentrations of substrates will affect ester production accordingly. Perhaps the most convenient and selective way to reduce ester production is applying tank overpressure, if necessary in combination with (slightly) lower fermentation temperatures, low wort free amino nitrogen (FAN) and glucose levels

and elevated wort aeration or wort lipid concentration (Verstrepen et al. 2003b). Enhancing ester production is slightly more complicated.

If it is possible, overpressure or wort aeration can be reduced. Otherwise, worts rich in glucose and nitrogen combined with higher fermentation temperatures and lower pitching rates or application of the drauflassen technique may prove helpful.

BIOSYNTHESIS OF ORGANIC ACIDS

Over hundred different organic acids have been reported in beer (Meilgaard 1975b). Important organic acids detected in beer include pyruvate, acetate, lactate, succinate, pyroglutamate, malate, citrate, α-ketoglutarate, and α-hydroxyglutarate; and the medium-chain length fatty acids, caproic (C6), caprylic (C8), and capric (C10) acid (Coote and Kirsop 1974, Meilgaard 1975b, Klopper et al. 1986). They influence flavor directly when present above their taste threshold and by their influence on beer pH. These components have their origin in raw materials (malt, hops) and are produced during the beer fermentation. Organic acids, which are excreted by yeast cells, are synthesized via amino acid biosynthesis pathways and carbohydrate metabolism. Especially, they are overflow products of the incomplete Krebs cycle during beer fermentation. Excretion of organic acids is influenced by yeast strain and fermentation vigor. Sluggish fermentations lead to lower levels of excretion. Pyruvate excretion follows the yeast growth: maximal concentration is reached just before the maximal yeast growth and is next taken up by the yeast and converted to acetate. Acetate is synthesized quickly during early fermentation and is later partially reused by the yeast during yeast growth. At the end of the fermentation, acetate is accumulated. The reduction of pyruvate results in the production of D-lactate of L-lactate (most yeast strains produce preferentially D-lactate). The highest amount of lactate is produced during the most active fermentation period.

The change in organic acid productivity by disruption of the gene encoding fumarase (*FUM1*) has been investigated and it has been suggested that malate and succinate are produced via the oxidative pathway of the TCA cycle under static and sake brewing conditions (Magarifuchi et al. 1995). Using a NAD^{+}-dependent isocitrate dehydrogenase gene (*IDH1*, *IDH2*) disruptant, approximately half of the succinate in sake mash was found to be synthesized via the oxidative pathway of the TCA cycle in sake yeast (Asano et al. 1999).

Sake yeast strains possessing various organic acid productivities were isolated by gene disruption (Arikawa et al. 1999). Sake fermented using the aconitase gene (*ACO1*) disruptant contained a twofold higher concentration of malate and a twofold lower concentration of succinate than that made using the wild-type strain. The fumarate reductase gene (*OSM1*) disruptant produced sake containing a 1.5-fold higher concentration of succinate, whereas the α-ketoglutarate dehydrogenase gene (*KGD1*) and fumarase gene (*FUM1*) disruptants gave lower succinate concentrations. In *S. cerevisiae*, there are two isoenzymes of fumarate reductase (FRDS1 and FDRS2), encoded by the *FRDS* and *OSM1* genes, respectively (Arikawa et al. 1998). Recent results suggest that these isoenzymes are required for the reox-

idation of intracellular NADH under anaerobic conditions, but not under aerobic conditions (Enomoto et al. 2002).

Succinate dehydrogenase is an enzyme of the TCA cycle and thus essential for respiration. In *S. cerevisiae*, this enzyme is composed of four nonidentical subunits, that is, the flavoprotein, the iron–sulfur protein, the cytochrome b_{560}, and the ubiquinone reduction protein encoded by the *SDH1*, *SDH2*, *SDH3*, and *SDH4* genes, respectively (Lombardo et al. 1990, Chapman et al. 1992, Bullis and Lamire 1994, Daignan-Fournier et al. 1994). Sdh1p and Sdh2p comprise the catalytic domain involved in succinate oxidation. These proteins are anchored to the inner mitochondrial membrane by Sdh3p and Sdh4p, which are necessary for electron transfer and ubiquinone reduction, and constitute the succinate:ubiquinone oxidoreductase (complex II) of the electron transport chain. Single or double disruptants of the *SDH1*, *SDH1b* (which is a homologue of the *SDH1* gene), *SDH2*, *SDH3,* and *SDH4* genes have been constructed and shown that the succinate dehydrogenase activity was retained in the *SDH2* disruptant and that double disruption of *SDH1* and *SDH2* or *SDH1b* genes is necessary to cause deficiency of succinate dehydrogenase activity in sake yeast (Kubo et al. 2000). The role of each subunit in succinate dehydrogenase activity and the effect of succinate dehydrogenase on succinate production using strains that were deficient in succinate dehydrogenase, have also been determined. The results suggested that succinate dehydrogenase activity contributes to succinate production under shaking conditions, but not under static and sake brewing conditions.

The medium-chain fatty acids account for 85–90% of the fatty acids in beer and impart an undesirable goaty, sweaty, and yeasty flavor (Chen 1980). These fatty acids are produced de novo by yeast during anaerobic fermentation and are not the result of β-oxydation of wort or yeast long-chain fatty acids. As a result, any change in fermentation conditions that promote the extent of yeast growth also favor increased levels of medium-chain fatty acids in beer. Higher temperature, increased wort oxygenation, and possibly elevated pitching rates are all effective in this respect (Boulton and Quain 2006). The presence of these medium-chain fatty acids in beer is also related to yeast autolysis (Masschelein 1981). Yeast autolytic off-flavors are stimulated at high temperatures, high yeast concentrations, and prolonged contact times at the end of primary fermentation and during secondary fermentation.

BIOSYNTHESIS OF VICINAL DIKETONES

Vicinal diketones are ketones with two adjacent carbonyl groups. During fermentations, these flavor-active compounds are produced as by-products of the synthesis pathway of isoleucine, leucine, and valine (ILV pathway) (see Fig. 33.3) and thus also linked to amino acid metabolism (Nakatani et al. 1984) and the synthesis of higher alcohols. They impart a "buttery", "butterscotch" aroma to alcoholic drinks. Two of these compounds are important in beer, that is, diacetyl (2,3-butanedione) and 2,3-pentanedione. Diacetyl is quantitatively more important than 2,3-pentanedione. It has a taste threshold in lager beer from 17 µg/L (Saison et al. 2009) to 150 µg/L (Meilgaard
Figure 33.3. The synthesis and reduction of vicinal diketones in *Saccharomyces cerevisiae*.

1975b), approximately 10 times lower than that of pentanedione (Wainwright 1973).

The excreted α-acetohydroxy acids are overflow products of the ILV pathway that are nonenzymatically degraded to the corresponding vicinal diketones (Inoue et al. 1968). Tetraploid gene dosage series for various *ILV* genes have been constructed and the obtained yeast strains were used to study the influence of the copy number of *ILV* genes on the production of vicinal diketones (Debourg et al. 1990, Debourg 2002). It was shown that the *ILV5* activity is the rate-limiting step in the ILV pathway and responsible for the overflow (Fig. 33.3). The nonenzymatic oxidative decarboxylation step is the rate-limiting step and proceeds faster at a higher temperature and a lower pH (Inoue and Yamamoto 1970, Haukeli and Lie 1978). The produced amount of α-acetolactate is very dependent on the used yeast strain. The production increases with increasing yeast growth. For a classical fermentation, 0.6 ppm α-acetolactate is formed (Delvaux 1998). At high aeration, this value can be increased to 0.9 ppm and in cylindro-conical fermentations tanks even to 1.2–1.5 ppm.

It has been shown that valine inhibits the synthesis of α-acetolactate through feedback inhibition (Magee and de Robinson-Szulmajster 1968). This inhibition is directed to the protein Ilv6p, which is the regulatory subunit of acetohydroxy acid synthase (the catalytic subunit encoded by *ILV2*)(Pang and Duggleby 1999, 2001). Because the uptake of valine is delayed in a normal beer fermentation, the suppressive effect of valine accounts for the postponed onset of total diacetyl (sum of actual diacetyl and α-acetolactate), and this effect persists longer in worts with high levels of FAN content. In contrast, low FAN levels give two diacetyl peaks as a result of the requirement for valine biosynthesis. Therefore, a minimum FAN level above the critical value of 50 ppm (Nakatani et al. 1984)

or 140 ppm (Pugh et al. 1997) should be maintained during the fermentation to ensure the presence of valine in the fermenting wort.

Yeast cells posses the necessary enzymes (reductases) to reduce diacetyl to acetoin and further to 2,3-butanediol, and 2,3-pentanedione to 2,3-pentanediol (Bamforth and Kanauchi 2004). These reduced compounds have much higher taste thresholds and have no impact on the beer flavor (Van Den Berg et al. 1983). The reduction reactions are yeast strain dependent. The reduction occurs at the end of the main fermentation and during the maturation. Sufficient yeast cells in suspension are necessary to obtain an efficient reduction. Yeast strains that flocculate early during the main fermentation needs a long maturation time to reduce the vicinal diketones. Diacetyl can be complexed using SO_2. These complexes cannot be reduced, but diacetyl can again be liberated at a later stage by aldehydes. This situation is especially applicable to yeast strains, which produce a lot of SO_2. Worts, which are produced using a high content of adjuncts, can be low in free amino acid content. These worts can give rise to a high diacetyl peak at the end of the fermentation.

There are several strategies, which can be chosen to reduce the vicinal diketones amount during fermentation:

1. Since the temperature has a positive effect on the reduction efficiency of the α-acetohydroxy acids, a warm rest period at the end of the main fermentation and a warm maturation are applied in many breweries. In this case, temperature should be well controlled to avoid yeast autolysis.
2. Since the rapid removal of vicinal diketones requires yeast cells in an active metabolic condition, the addition of 5–10% Krausen (containing active, growing yeast) is a procedure, which gives enhanced transformation of vicinal diketones (NN 2000). This procedure can lead to

overproduction of hydrogen sulfide, depending upon the proportions of threonine and methionine carried forward from primary fermentation.

3. Heating up the green beer to a high temperature (90°C) and hold it there for a short period (ca. 7–10 min) to decarboxylate all excreted α-acetohydroxy acids. To avoid cell autolysis, yeast cells are removed by centrifugation prior to heating up. The vicinal diketones can be further reduced by immobilized yeast cells in a few hours (typically at 4°C) (see further).

4. *Adding the enzyme α-acetolactate decarboxylase* (Godtfredsen et al. 1984, Rostgaard-Jensen et al. 1987): This enzyme decarboxylates α-acetolactate directly into acetoin (see Fig. 33.3). It is not present in *S. cerevisiae*, but has been isolated from various bacteria such as *Enterobacter aerogenes*, *Aerobacter aerogenes*, *Streptococcos lactis, Lactobacillus casei, Acetobacter aceti,* and *Acetobacter pasteurianus*. It has been shown that the addition of α-acetolactate decarboxylase from *L. casei* can reduce the maturation time to 22 hours (Godtfredsen et al. 1983, 1984). An example of a commercial product is Maturex L from Novo Nordisk (Denmark) (Jensen 1993). Maturex L is a purified α-acetolactate decarboxylase produced by a genetically modified strain of *Bacillus subtilis*, which has received the gene from *Bacillus brevis*. The recommended dosage is 1 à 2 kg per 1000 hL wort, to be added to the cold wort at the beginning of fermentation.

5. Using genetic modified yeast strains:

    a. Introducing the bacterial α-acetolactate decarboxylase gene into yeast chromosomes (Fujii et al. 1990, Suihko et al. 1990, Blomqvist et al. 1991, Enari et al. 1992, Linko et al. 1993, Yamano et al. 1994, Tada et al. 1995, Onnela et al. 1996). Transformants possessed a very high α-acetolactate decarboxylase activity that reduced the diacetyl concentration considerably during beer fermentations.

    b. Modifying the biosynthetic flux through the ILV pathway by partially deactivation of *ILV2*. Spontaneous mutants resistant to the herbicide sulfometuron methyl have been selected. These strains showed a partial inactivation of the α-acetolactate synthase activity and some mutants produced 50% less diacetyl compared to the parental strain (Gjermansen et al. 1988).

    c. Increasing the flux of α-acetolactate acid isomerorecuctase activity encoded by the *ILV5* gene (Dillemans et al. 1987). Since α-acetolactate acid isomerorecuctase activity is responsible for the rate-limiting step, increasing its activity reduces the overflow of α-acetolactate. A multicopy transformant resulted in a 70% decreased production of vicinal diketones (Villaneuba et al. 1990), whereas an integrative transformant gave a 50% reduction (Goossens et al. 1993). A tandem integration of multiple *ILV5* copies resulted also in elevated transciction in a polyploidy industrial yeast strain (Mithieux and Weiss 1995). Vicinal diketones production could be reduced by targeting the mitochondrial Ilv5p to the cytosol (Omura 2008).

SECONDARY FERMENTATION

During the secondary fermentation or maturation of beer, several objectives should be realized:

-   Sedimentation of yeast cells
-   Improvement of the colloidal stability by sedimentation of the tannin–protein complexes
-   Beer saturation with carbon dioxide
-   Removal of unwanted aroma compounds
-   Excretion of flavor-active compounds from yeast to give body and depth to the beer
-   Fermentation of the remaining extract
-   Improvement of the foam stability of the beer
-   Adjustment of the beer color (if necessary) by adding coloring substances (e.g., caramel)
-   Adjustment of the bitterness of beer (if necessary) by adding hop products

In the presence of yeast, the principal changes that occur are the elimination of undesirable flavor compounds, such as vicinal diketones, hydrogen sulfide, and acetaldehyde, and the excretion of compounds enhancing the flavor fullness (body) of beer.

VICINAL DIKETONES

In traditional fermentation lagering processes, the elimination of vicinal diketones required several weeks and determined the length of the maturation process. Nowadays, the maturation phase is much shorter since strategies are used to accelerate the vicinal diketones removal (see the preceding text). Diacetyl is used as a marker molecule. The objective during lagering is to reduce the diacetyl concentration below its taste threshold (<0.10 mg/mL).

HYDROGEN SULFIDE

Sulfite and hydrogen sulfide are intermediates in the biosynthesis of the sulfur-containing amino acids methionine and cysteine (Van Haecht and Dufour 1995, Duan et al. 2004). Hydrogen sulfide plays an important role during maturation. Inorganic sulfate is taken up by the yeast cells via a permease. Subsequently, it is reduced to sulfide via the intermediates adenylyl sulfate, phosphoadenylyl sulfate and sulfite (see Fig. 33.4). H_2S and SO_2, which are not incorporated in S-containing amino acids, are excreted by the yeast cell during the growth phase (Ryder and Masschelin 1983, Thomas and Surdin-Kerjan 1997). The excreted amount depends on the used yeast strain, the sulfate content of the wort and the growth conditions (Romano and Suzzi 1992). Methionine causes decreased production of sulfur compounds by feedback inhibition, while threonine increases the production (Thomas and Surdin-Kerjan 1997). H_2S and SO_2 can also be formed from the catabolism of S-containing amino acids (Dual et al. 2004). The production of H_2S and SO_2 depends on the yeast strain, sulfate content in the wort, and growth conditions. The production of H_2S could be reduced by the expression of cystathione synthase genes from *S. cerevisiae* in a brewing yeast strain (Tezuka et al. 1992).
Figure 33.4. The remethylation, transulfuration, and sulfur assimilation pathways. Genes and enzymes catalyzing individual reactions are as follows: 1, sulfate permease; 2, ATP sulfurylase; 3, *MET14*: adenylylsulfate kinase (EC 2.7.1.25); 5, *MET10*: sulfite reductase (EC 1.8.1.2); 6, sulfite permease; 7, *MET17*: *O*-acetylhomoserine (thiol)-lyase (EC 2.5.1.49); 8, *CYS4*: cystathionine β-synthase (CBS; EC 4.2.1.22); 9, *CYS3*: cystathionine γ-lyase (EC 4.4.1.1), 10, *MET6*: methionine synthase (EC 2.1.1.14); 11, *SAM1* and *SAM2*: *S*-adenosylmethionine synthetase (EC 2.5.1.6); 12, *SAH1*: *S*-adenosylhomocysteine hydrolase (EC 3.3.1.1); 13, *SHM1* and *SHM2*: serine hydroxymethyltransferase (SHMT; EC 2.1.2.1); 14, *MET12* and *MET13*: methylenetetrahydrofolate reductase (MTHFR; EC 1.5.1.20). "X" represents any methyl group acceptor; THF, tetrahydrofolate; CH_2-THF, 5,10-methylenetetrahydrofolate; CH_3-THF, 5-methyltetrahydrofolate. (Partly adapted from Chan and Appling 2003.)

At the end of the primary fermentation and during the maturation, the excess H_2S is reutilized by the yeast. A warm conditioning period at 10 à 12°C may be used to remove excessive levels of H_2S.

Brewing yeasts produce H_2S when they are deficient in the vitamin pantothenate (Walker 1998). This vitamin is a precursor of coenzyme A, which is required for metabolism of sulfate into methionine. Therefore, panthothenate deficiency may result in an imbalance in sulfur amino acid biosynthesis, leading to excess sulfate uptake and excretion of H_2S (Slaughter and Jordan 1986).

Sulfite is a versatile food additive used to preserve a large range of beverages and foodstuffs. In beer, sulfite has a dual purpose, acting both as an antioxidant and an agent for masking of certain off-flavors. Some of the flavor stabilizing properties of sulfite is suggested to be due to complex formation of bisulfate with varying carbonyl compounds, of which some would give rise to off-flavors in bottled beer (Dufour 1991). Especially,

the unwanted carbonyl *trans*-2-nonenal has received particular attention, since it is responsible for the "cardboard" flavor of some types of stale beer. It has been suggested that it would be better to use a yeast strain with reduced sulfite excretion during fermentation and to add sulfite at the point of bottling to ensure good flavor stability (Francke Johannesen et al. 1999). Therefore, a brewer's yeast disabled in the production of sulfite has been constructed by inactivating both copies of the two alleles of the *MET14* gene (which encodes for adenylylsulfate kinase). Fermentation experiments showed that there was no qualitative difference between yeast-derived and artificially added sulfite, with respect to *trans*-2-nonenal content and flavor stability of the final beer.

The elimination of the gene encoding sulfite reductase (*MET10*) in brewing strains of *Saccharomyces* results in increased accumulation of SO_2 in beer (Hansen and Kielbrandt 1996a). The inactivation of *MET2* resulted into elevated sulfite

concentrations in beer (Hansen and Kielbrandt 1996b). Beers produced with increased levels of sulfite showed an improved flavor stability.

ACETALDEHYDE

Aldehydes—in particular, acetaldehyde (green apple-like flavor)—have an impact on the flavor of green beer. The accumulation of acetaldehyde is dependent on the kinetic properties of enzymes responsible for its formation (pyruvate decarboxylase and acetaldehyde dehydrogenase) and dissimilation (alcohol dehydrogenase) (Boulton and Quain 2006). Acetaldehyde synthesis is linked to yeast growth (Geiger and Piendl 1976). Its concentration is maximal at the end of the growth phase and is reduced at the end of the primary fermentation and during maturation by the yeast cells. As with diacetyl, levels may be enhanced if yeast metabolism is stimulated during transfer, especially by oxygen ingress. Removal also requires the presence of enough active yeast. Fermentations with early flocculating yeast cells can result in too high acetaldehyde concentrations at the end.

DEVELOPMENT OF FLAVOR FULLNESS

During maturation, the residual yeast will excrete compounds (i.e., amino acids, phosphates, peptides, nucleic acids, ...) into the beer. The amount and "quality" of these excreted materials depend on the yeast concentration, yeast strain, its metabolic state and the temperature (NN 2000). Rapid excretion of material is best achieved at a temperature of 5–7°C during 10 days (Van de Meersche et al. 1977).

When the conditioning period is too long or when the temperature is too high, yeast cell autolysis will occur. Some enzymes are liberated (e.g., α-glucosidase), which will produce glucose from traces of residual maltose (NN 2000). At the bottom of a fermentation tank, the amount of α-amino-nitrogen can rise to 40–10,000 mg/L, which account for an increase of 30 mg/L for the total beer volume. The increase in amino acid concentration in the beer has a positive effect on the flavorfullness of the beer. Undesirable medium-chain fatty acids can also be produced in significant amounts if the maturation temperature is too high (Masschelein 1981). Measurement of these compounds indicates the level of autolysis and permits the determination of the most appropriate conditioning period and temperature.

BEER FERMENTATION USING IMMOBILIZED CELL TECHNOLOGY

The advantages of continuous fermentation—such as greater efficiency in utilization of carbohydrates and better use of equipment—led also to the development of continuous beer fermentation processes. Since the beginning of the twentieth century, many different systems using suspended yeast cells have been developed. The excitement for continuous beer fermentation led—especially during the 1950 and 1960s—to the development of various interesting systems. These systems can be classified as (i) stirred *versus* unstirred tank reactors, (ii)

single-vessel systems versus a number of vessels connected in series, (iii) vessels that allow yeast to overflow freely with the beer ("open system") versus vessels that have abnormally high yeast concentrations ("closed" or "semiclosed system") (Wellhoener 1954, Coutts 1957, Bishop 1970, Hough et al. 1982,). However, these continuous beer fermentation processes were not commercially successful due to many practical problems, such as the increased danger of contamination (not only during fermentation but also during storage of wort in supplementary holdings tanks that are required since the upstream and downstream brewing processes are usually not continuous), changes in beer flavor (Thorne 1968) and a poor understanding of the beer fermentation kinetics under continuous conditions. One of the well-known exceptions is the successful implementation of a continuous beer production process in New Zealand by Morton Coutts (Dominion Breweries), which is still in use today (Coutts 1957, Hough et al. 1982).

In the 1970, there was a revival in developing continuous beer fermentation systems due to the progress in research on immobilization bioprocesses using living cells. Immobilization gives fermentation processes with high cell densities, resulting in a drastic increase in fermentation productivities compared to the traditional time-consuming batch fermentation processes.

The last 30 years, ICT has been extensively examined and some designs have reached already commercial exploitation. Immobilized cell systems are heterogeneous systems in which considerable mass transfer limitations can occur, resulting in a changed cell yeast metabolism. Therefore, successful exploitation of ICT needs a thorough understanding of mass transfer and intrinsic yeast kinetic behavior of these systems.

CARRIER MATERIALS

Cell immobilization can be classified into four categories based on the mechanism of cell localization and the nature of support material: (i) attachment to the support surface, which can be spontaneous or induced by linking agents; (ii) entrapment within a porous matrix; (iii) containment behind or within a barrier; and (iv) self-aggregation, naturally or artificially induced (Karel et al. 1985, Willaert and Baron 1996). Various cell immobilization carrier materials have been tested and used for beer production/bioflavoring. Selection criteria are summarized in Table 33.5. Depending on the particular application, reactor type and operational conditions, some selection criteria will be more appropriate. Examples of selected carrier materials for particular applications are tabulated in Table 33.6.

Cell immobilization by self-aggregation is based on the formation of cell clumps or flocs. Actually, flocs are formed at the end of the primary fermentation when flocculent strains are used. Flocculent strains can also be used in continuous fermentation systems (see "Coutts continuous beer fermentation system" described in the preceding text). Very high yeast concentrations may be achieved by the use of inclined tubes, still zones around outlet pipes and by holding the yeast in a filter (Hough et al. 1982). Growth of the sedimentary yeast may be controlled by the amount of air injected, while carbon dioxide is used to cause some mixing. A flocculent strain has also been used in the tower

Table 33.5. Selection Criteria for Yeast Cell Immobilization Carrier Materials

- High cell mass loading capacity
- Easy access to nutrient media
- Simple and gentle immobilization procedure
- Immobilization compounds approved for food applications
- High surface area-to-volume ratio
- Optimum mass transfer distance from flowing media to centre of support
- Mechanical stability (compression, abrasion)
- Chemical stability
- Highly flexible: rapid start-up after shut-down
- Sterilizable and reusable
- Suitable for conventional reactor systems
- Low shear experienced by cells
- Easy separation of cells and carrier from media
- Readily up-scalable
- Economically feasible (low capital and operating costs)
- Desired flavor profile and consistent product
- Complete attenuation
- Controlled oxygenation
- Control of contamination
- Controlled yeast growth
- Wide choice of yeast

Source: Nedovic et al. (2005) and Verbelen et al. (2010).

fermenter system, which comprises a vertical tube into the base of which wort is pumped (Royston 1966). The sedimentary yeast forms a solid plug at the base of the vessel and through it the wort permeates. Fermentation proceeds as the wort rises, with the rate of wort injection being so adjusted that at the top of the tower the wort is completely fermented.

Yeast flocculation is a reversible, asexual, and calcium-dependent process in which cells adhere to form flocs consisting of thousands of cells (Stratford 1989, Bony et al. 1997, Jin and Speers 1999). Many fungi contain a family of cell wall "adhesines" (which are glycoproteins) that confer unique adhesion properties (Teunissen and Steensma 1995, Guo et al. 2000, Hoyer 2001, Sheppard et al. 2004). These molecules are required for the interactions of fungal cells with each other (flocculation and filamentation) (Teunissen and Steensma 1995, Lo and Dranginis 1998, Guo et al. 2000, Viyas et al. 2003), with inert surfaces such as agar and plastic (Gaur and Klotz 1997, Lo and Dranginis 1998, Reynolds and Fink 2001, Li and Palecek 2003) and with mammalian tissues/cells (Cormack et al. 1999, Staab et al. 1999, Fu et al. 2002, Li and Palecek 2003). They are also crucial for the formation of fungal biofilms (Baillie and Douglas 1999, Reynolds and Fink 2001, Green et al. 2004). The adhesin proteins in *S. cerevisiae* are encoded by *FLO* genes, including *FLO1*, *FLO5*, *FLO9, FLO10*, and *FLO11* (Verstrepen et al. 2004). These proteins are called flocculins (Caro et al. 1997) because these proteins promote cell–cell adhesion to form multicellular clumps that sediment out of solution.

The flocculation phenomenon is genetically controlled by 33 genes (Teunissen and Steensma 1995). Recently, the five members of the *FLO*-adhesine family were studied by selectively

overexpressing each *FLO* gene in the laboratory strain S288C (Van Mulders et al. 2009). As all *FLO* genes are transcriptionally silent in the S288C-strain background, each *FLO* gene can be activated one by one and each resultant phenotype can be investigated. The *FLO1*, *FLO5*, *FLO9,* and *FLO10* genes share considerable sequence homology. The member proteins of the adhesin family have a modular configuration that consists of three domains (A, B, and C) and an *N*-terminal secretory sequence that must be removed as the protein moves through the secretory pathway to the plasma membrane (Hoyer et al. 1998). The *N*-terminal domain (A) is involved in sugar recognition (Kobayashi et al. 1998). The adhesins undergo several posttranslational modifications, that is, *N*- and *O*-glycosylations. They move from the endoplasmic reticulum (ER) through the Golgi and pass through the plasma membrane and find their final destination in the cell wall, where they are anchored by a glycosyl phosphatidylinositol (GPI) (Teunissen et al. 1993a, 1993b, Bidard et al. 1994, Bony et al. 1997, Hoyer et al. 1998). The GPI anchor is added to the *C*-terminus in the ER, and mannose residues are added to the many serine and threonine residues in domain B in the Golgi (Udenfriend and Kodukula 1995, Bony et al. 1997, Frieman et al. 2002, De Groot et al. 2003). The *FLO1* gene product (Flo1p) has been localized at the cell surface by immunofluorescent microscopy (Bidard et al. 1995). The amount of Flo proteins in flocculent strains increased during batch yeast growth and the Flo1p availability at the cell surface determined the flocculation degree of the yeast. Flo proteins are polarly incorporated into the cell wall at the bud tip and the mother–daughter neck junction (Bony et al. 1997). The transcriptional activity of the flocculation genes is influenced by the nutritional status of the yeast cells as well as other stress factors (Verstrepen et al. 2003a). This implies that during beer fermentation, flocculation is affected by numerous parameters such as nutrient conditions, dissolved oxygen, pH, fermentation temperature, and yeast handling and storage conditions.

APPLICATIONS OF ICT IN THE BREWING INDUSTRY

Beer production with immobilized yeast has been the subject of research for approximately 40 years, but has so far found limited application in the brewing industry, because of engineering problems, unrealised cost advantages, microbial contaminations, and an unbalanced beer flavor (Linko et al. 1998, Brányik et al. 2005, Nedovic et al. 2005, Willaert and Nedovic 2006, Verbelen et al. 2010). The ultimate aim of this research is the production of beer, of desired quality, within 1–3 days. Traditional beer fermentation systems use freely suspended yeast cells to ferment wort in an unstirred batch reactor. The primary fermentation takes approximately 7 days with a subsequent secondary fermentation (maturation) of several weeks. A batch culture system employing immobilization could benefit from an increased rate of fermentation. However, it appears that in terms of increasing productivity, a continuous fermentation system with immobilization would be the best method (Verbelen et al. 2006). An important issue of the research area is to whether beer can be produced by immobilized yeast in continuous culture with the same characteristic as the traditional method.

Table 33.6. Some Selected Applications of Cell Immobilization Systems Used for Beer Production

Carrier Material	Reactor Type	Reference
Flavor maturation		
Calcium alginate beads	Fixed bed	Shindo et al. (1994)
DEAE-cellulose	Fixed bed	Pajunen and Grönqvist (1994)
Polyvinyl alcohol beads	Fixed bed	Smogrovicová et al. (2001)
Porous glass beads	Fixed bed	Linko et al. (1993), Aivasidis (1996)
Alcohol-free beer		
DEAE-cellulose beads	Fixed bed	Collin et al. 1991, Lomni et al. 1990
Porous glass beads	Fixed bed	Aivasidis et al. (1991)
Silicon carbide rods	Monolith reactor	Van De Winkel et al. (1991)
Acidified wort		
DEAE-cellulose beads	Fixed bed	Pittner et al. (1993)
Main fermentation		
Calcium alginate beads	Gas lift	White and Portno (1979), Nedovic et al. (1997)
Calcium pectate beads	Gas lift	Smogrovicová et al. (1997)
κ-Carrageenan beads	Gas lift	Mensour et al. (1996), Decamps et al. (2004)
Ceramic beads	Fixed bed	Inoue (1995)
Corncobs	Gas lift	Brányik et al. (2006a)
Gluten pellets	Fixed bed	Bardi et al. 1997
Polyvinyl alcohol beads	Gas lift	Smogrovicová et al. (2001)
Polyvinyl alcohol Lentikats®	Gas lift	Smogrovicová et al. (2001), Bezbradica et al. (2007)
Polyvinyl chloride granules	Gas lift	Moll et al. (1973)
Porous glass beads	Fixed bed	Virkajärvi and Krönlof (1998)
Porous chitosan beads	Fluidized bed	Unemoto et al. (1998), Maeba et al. (2000)
Silicon carbide rods	Monolith reactor	Andries et al. (1996)
Spent grains	Gas lift	Brányik et al. (2002, 2004)
Stainless steel fibre cloths	Gas lift	Verbelen et al. (2006)
Wood (aspen beech) chips	Fixed bed	Linko et al. (1997), Kronlöf and Virkajärvi (1999), Pajunen et al. (2001)

Started in 1971, one of the first ICT systems for the fermentation and maturation of beer was developed by TREPAL (the R&D Centre of the Konenbourg Brewery and the European Brewery) with INSA (Institut National des Sciences Appliquées, Toulouse, France) and INRA (Institus National des Recherche Agronomique, Dijon, France) (Moll et al. 1973, Moll and Dueurtre 1996, Moll 2006). A continuous pilot installation for fermentation and maturation of beer with a flow rate of 5 L/h was developed and worked for 9 months without any microbial contamination. Around the same time, Narziss and Hellich (1971) developed an ICT process where yeast cells were immobilized in kieselguhr (which is widely used in the brewing industry as a filter aid) and a kieselguhr filter was employed as bioreactor (called the "bio-brew bioreactor"). Their yeast cell immobilization method was based on a method for the immobilization of enzymes (Berdelle-Hilge 1966). From the beginning of the nineteen seventies, various systems have been developed and some have been implemented on an industrial scale.

ICT processes have been developed for (i) the flavor maturation of green beer, (ii) the production of alcohol-free or low-alcohol beer, (iii) the production of acidified wort using immobilized lactic acid bacteria, and (iv) the continuous beer fermentation (Brányik et al. 2005, Verbelen et al. 2006, Willaert and Nedovic 2006, Willaert 2007, Verbelen et al. 2010).

Flavor Maturation of Green Beer

The objective of flavor maturation is the removal of diacetyl and 2,3-pentanedione, and their precursors α-acetolactate and α-acetohydroxybutyrate, which are produced during the main fermentation (see the preceding text). The conversion of α-acetohydroxy acids to the vicinal diketones is the rate-limiting step. This reaction step can be accelerated by heating the beer—after yeast removal—to 80–90°C during a couple of minutes. The resulting vicinal diketones are subsequently reduced by immobilized cells into their less-flavor-active compounds.

The traditional maturation process is characterized by a near-zero temperature, low pH and low yeast concentration, resulting in a very long maturation period of 3–4 weeks. Different strategies have been developed to accelerate diacetyl removal (see Section "Vicinal diketones"). One of the techniques is the use of an ICT process to reduce the maturation period to about 2 hours.

Two continuous maturation systems have been implemented industrially so far: one at Sinebrychoff Brewery (Finland, capacity: 1 million hL per year) (Pajunen 1995) and another system, developed by Alfa Laval and Schott Engineering (Mensour et al. 1997). They are both composed of a separator (to prevent growing yeast cells in the next stages), an anaerobic heat treatment unit (to accelerate the chemical conversion of α-acetolactate to diacetyl, but also the partial directly conversion to acetoin), and a packed bed reactor with yeast immobilized on DEAE-cellulose granules or porous glass beads (to reduce the remaining diacetyl), respectively (Yamauchi et al. 1994). Later on, the DEAE-cellulose carriers were replaced by cheaper wood chips (Virkajärvi 2002). The heat treatment has been replaced by an enzymatic transformation in a fixed bed reactor in which the α-acetolactate decarboxylase is immobilized in special multilayer capsules, followed by the reduction of diacetyl by yeast in a second packed bed reactor (Nitzsche et al. 2001).

Production of Alcohol-Free or Low-Alcohol Beer

The classical technology to produce alcohol-free or low-alcohol beer is based on the suppression of alcohol formation by arrested batch fermentation (Narziss et al. 1992). However, the resulting beers are characterized by an undesirable wort aroma, since the wort aldehydes have only been reduced to a limited degree (Collin et al. 1991, Debourg et al. 1994, van Iersel et al. 1998). The reduction of these wort aldehydes can be quickly achieved by a short contact time with immobilized yeast cells at a low temperature without undesirable cell growth and ethanol production. A disadvantage of this short contact process is the production of only a small amount of desirable esters.

Controlled ethanol production for low-alcohol and alcohol-free beers have been successfully achieved by partial fermentation using DEAE-cellulose as carrier material, which was packed in a column reactor (Collin et al. 1991, Van Dieren 1995). This technology has been successfully implemented by Bavaria Brewery (The Netherlands) to produce malt beer on an industrial scale (150,000 hL/year) (Pittner et al. 1993). Several other companies—that is, Faxe (Denmark), Ottakringer (Austria), and a Spanish brewery—have also implemented this technology (Mensour et al. 1997). In Brewery Beck (Germany), a fluidized-bed pilot scale reactor (8 hL/day) filled with porous glass beads was used for the continuous production of nonalcoholic beer (Aivasidis et al. 1991, Breitenbücher and Mistler 1995, Aivasidis 1996). Yeast cells immobilized in silicon carbide rods and arranged in a multichannel loop reactor (Meura, Belgium) have been used to produce alcohol-free beer at pilot scale by Grolsch Brewery (The Netherlands) and Guinness Brewery (Ireland) (Van De Winkel 1995).

Nuclear mutants of *S. cerevisiae* that are defective in the synthesis of tricarboxylic acid cycle enzymes; that is, fumarase (Kaclíková et al. 1992) or 2-oxoglutarate dehydrogenase (Mockovciaková et al. 1993) have been immobilized in calcium pectate gel beads and used in a continuous process for the production of nonalcoholic beer (Navrátil et al. 2000). These strains produced minimal amounts of ethanol and they were also able to produce much lactic acid (up to 0.64 g/dm^3).

Production of Acidified Wort Using Immobilized Lactic Acid Bacteria

The objective of this technology is the acidification of the wort according to the "Reinheidsgebot", before the start of the boiling process in the brewhouse. An increased productivity of acidified wort has been obtained using immobilized *Lactobacillus amylovorus* on DEAE-cellulose beads (Pittner et al. 1993, Meersman 1994). The pH of wort was reduced below a value of 4.0 after contact times of 7–12 minutes using a packed-bed reactor in downflow mode. The produced acidified wort was stored in a holding tank and used during wort production to adjust the pH.

Continuous Main Fermentation

During the main fermentation of beer, not only ethanol is being produced but also a complex mixture of flavor-active secondary metabolites, of which the higher (or fusel) alcohols and esters are the most important (Verbelen et al. 2010). In addition, diacetyl and some sulfury compounds can cause off-flavors. Since this complex flavor profile is closely related to the amino acid metabolism and consequently to the growth of the yeast cells, differences in the growth metabolic state between freely suspended and immobilized yeast cell systems are most probably responsible for the majority of alterations in the beer flavor. For that reason, it is important that the physiological and metabolic state of the yeast in conventional batch systems is mimicked as much as possible during the continuous fermentation with immobilized yeast. In the continuous mode of operation, cells are not exposed to significant alterations of the environment, influencing the metabolism of the cells and consequently the flavor. Hence, the microbial population of continuous systems lacks the different growth phases of a batch culture. To imitate the batch process as much as possible, plug-flow reactors or a series of reactors can be used. As can be assumed, both the continuous mode of operation and the immobilization of yeast cells can influence the beer flavor.

The Japanese brewery Kirin developed a multistage continuous fermentation process (Inoue 1995, Yamauchi et al. 1994, Yamauchi and Kasahira 1995). The first stage is a stirred tank reactor for yeast growth, followed by packed-bed fermenters, and the final step is a packed-bed maturation column. The first stage ensures adequate yeast cell growth with the desirable FAN consumption. Ca-alginate was initially selected as carrier material to immobilize the yeast cells. These alginate beads were later replaced by ceramic beads ("Bioceramic®"). This system allowed to produce beer within 3–5 days.

The engineering company Meura (Belgium) developed a reactor configuration with a first stage with immobilized yeast cells where partially attenuation and yeast growth occurs, followed by a stirred tank reactor (with free yeast cells) for complete attenuation, ester formation, and flavor maturation (Andries et al. 1996, Masschelein and Andries 1995). Silicon carbide rods are used in the first reactor as immobilization carrier material. The stirred tank (second reactor) is continuously inoculated by free cells that escape from the first immobilized yeast cell reactor.

Labatt Breweries (Interbrew, Canada) in collaboration with the Department of Chemical and Biochemical Engineering at the University of Western Ontario (Canada) developed a continuous system using κ-carrageenan immobilized yeast cells in an airlift reactor (Mensour et al. 1995, 1996, 1997). Pilot scale research showed that full attenuation was reached in 20–24 hours with this system compared to 5–7 days for the traditional batch fermentation. The flavor profile of the beer produced using ICT was similar to the batch fermented beer.

Hartwell Lahti and VTT Research Institute (Finland) developed a primary fermentation system using ICT on a pilot scale of 600 L/day (Kronlöf and Virkajärvi 1999). Woodchips were used as the carrier material that reduced the total investment cost by one-third compared to more expensive carriers. The results showed that fermentation and flavor formation were very similar compared to a traditional batch process, although the process time was reduced to 40 hours.

Andersen et al. (1999) developed a new ICT process in which the concentration of carbon dioxide is controlled in a fixed-bed reactor in such a way that the CO_2 formed is kept dissolved and is removed from the beer without foaming problems. DEAE-cellulose was used as carrier material. High-gravity beer of acceptable quality has been fermented in 20 hours at a capacity of 50 L/h.

A well-explored concept for main beer fermentation is the use of a gas-lift bioreactor system (see Table 33.6). In this system, mixing established by the circulation of liquid and solid phases, provided high liquid circulation rates, low shear environment, and good mass transfer properties (Siegel and Robinson 1992, Vunjak-Novakovic et al. 1992, Chisti and Moo-Young 1993, Baron et al. 1996). Additionally, they possess the following positive characteristics: high loadings of solids, simple construction, low risk of contamination, easy adjustment and control of operational parameters and simple capacity enlargement (Vunjak-Novakovic et al. 1998). Various carrier materials for gas-lift bioreactors have been studied to perform the main fermentation (see Table 33.6).

The optimization of temperature, wort gravity, feed volume, and wort composition seems to be an important tool for the control of the flavor-active compounds formation in immobilized beer fermentation systems (Verbelen et al. 2006, 2010, Willaert and Nedovic 2006, Brányik et al. 2008). Many researchers have concluded that the optimization of aeration during continuous fermentation is essential for the quality of the final beer (Virkajärvi et al. 1999). Oxygen is needed for the formation of unsaturated fatty acids and sterols that needed for growth (Depraetere et al. 2003). However, excess oxygen will lead to low ester production but to excessive diacetyl, acetaldehyde, and fusel alcohol formation (Okabe et al. 1992, Wackerbauer et al. 2003, Brányik et al. 2004). It is possible to adjust the flavor of the produced beer by ensuring the adequate amount of dissolved oxygen by sparging with a mixture of air, nitrogen, or carbon dioxide (Kronlöf and Linko 1992, Brányik et al. 2004). However, it remains difficult to predict the right amount of oxygen because the oxygen availability to the immobilized yeast cells is dependent of external and internal mass transfer limitations (Willaert and Baron 1996, Willaert et al. 2004).

Also, the reactor design, the carrier, and yeast strain can have a dominant effect on flavor formation (Cop et al. 1989, Linko, et al. 1997, Smogrovicová and Dömény 1999, Tata et al. 1999, Virkajärvi and Pohjala 2000).

Rye Constituents and Their Impact on Rye Processing

T. Verwimp, C. M. Courtin, and J. A. Delcour

CLASSIFICATION

Rye (*Secale cereale* L.), member of the grass family (Gramineae) and typically classified into winter and spring varieties, is a diploid, seven-pair chromosome cereal, with tetraploid varieties sometimes being produced artificially. While cultivated rye varieties are less numerous than those of other cereal crops, most varieties are mixed populations because of cross-pollination.

PRODUCTION

Although rye production (15 million tons) is low compared with the 2003 total world production of the three major cereals, wheat, corn, and rice (556, 638, and 589 million tons, respectively) (FAO 2004), rye's low soil and fertilization requirements as well as its relatively good overwintering ability guarantee continuing interest in the cereal, as it can be cultivated in areas generally not suited for other cereal crops. In 2003, high amounts of rye were produced by Russia (4.1 million tons), Poland (3.2 million tons), Germany (2.3 million tons), and Belarus (1.4 million tons) (FAO 2004), making this cereal crop of major importance in parts of

Europe and Asia, but of less importance in America. Production has remained fairly constant, but with a downward trend, during the past 10 years.

THE RYE KERNEL

The main components of the rye kernel are, from the outside to the inside, the hull, pericarp, testa, nucellar epidermis, aleurone and starchy endosperm, and the germ. As the hull threshes free, the pericarp is the actual outer part of the grain, surrounding the seed and consisting of different layers, ranging from the epidermis, hypodermis, and cross cells to tube cells. The latter adhere to the testa or seed coat, which is in turn lined with the nucellar epidermis. The aleurone cells are located beneath the nucellar epidermis, forming the outermost layer of the endosperm tissue, and merge with the scutellum of the germ. The starchy endosperm is composed of three main cell types, that is, the subaleurone or peripheral cells, the prismatic cells, and the central endosperm cells, and contains two major storage reserves. The subaleurone cells contain high levels of storage protein, while the prismatic cells contain high levels of starch granules (Shewry and Bechtel 2001). The pericarp, testa, and nucellar epidermis form the botanical bran and are separated from the starchy endosperm together with the aleurone layer and the germ in the milling process, forming the technical or miller's bran.

RYE CONSTITUENTS

The major rye constituents are starch and nonstarch polysaccharides and protein. Its lipids, vitamins, and minerals are minor constituents (Table 34.1).

Starch

Starch Composition

Starch granules are mainly composed of two types of polymers, amylose, and amylopectin. In general, amylose is an essentially linear polymer consisting of α-D-glucopyranose residues linked by α-1,4 bonds with few (<1%; Ball et al. 1996) α-1,6 bonds. Amylose occurs in both free and lipid-complexed forms. Lipid-

complexed amylose may be present in native starch, but is possibly also formed during gelatinization of starch (Andreev et al. 1999, Morrison 1995). Amylose contents in rye starch vary from 12 to 30% (Andreev et al. 1999, Fredriksson et al. 1998, Mohammadkhani et al. 1998, Wasserman et al. 2001). Berry et al. (1971) reported the rye amylose fraction to have a molecular weight of about 220 k.

Amylopectin is a highly branched polymer consisting of α-D-glucopyranose residues linked by α-1,4 linkages with 4–5% (according to Keetels et al. 1996) α-1,6 linkages. Berry et al. (1971) showed that rye amylopectin has 4.8% branching, with branch points about every 21 glucose units on average. The chains of amylopectin can be classified into three types: A-, B-, and C-chains. The A-chains are unbranched outer chains and are attached to the inner B-chains through their potential reducing end. In their turn, the B-chains are attached to other B-chains or to the single C-chain through their potential reducing end. The C-chain is the only chain carrying a reducing end group. Lii and Lineback (1977) reported an A-chain to B-chain ratio of 1.71–1.81 and an average unit chain length of 26 for rye amylopectin.

Minor components of starch granules are lipids, proteins, phosphorus, and ash.

Starch Structure

Rye starch has a bimodal particle size distribution comprising a major population of large, lenticular A-type granules ($>10\,\mu$m, 85%), and a minor population of small, spherical B-type granules ($>10\,\mu$m, 15%) (Schierbaum et al. 1991, Verwimp et al. 2004). Rye A-type starch granules have larger average particle sizes and broader particle size distribution profiles than their wheat counterparts (Fredriksson et al. 1998, Verwimp et al. 2004).

In starch granules, the amylose and amylopectin molecules are radially ordered, with their single reducing end groups towards the center, or hilum. Ordering of crystallites within the starch granule causes optical birefringence, and a Maltese cross can be observed under polarized light. Starch granules are made up of alternating semicrystalline and amorphous growth rings, arranged concentrically around the hilum. The amorphous growth

Table 34.1. Composition of the Rye Kernel

Constituent	Content (%)	References

ring contains amylose and probably less-ordered amylopectin (Morrison 1995). The semicrystalline growth ring consists of alternating crystalline and amorphous lamellae. The crystalline lamellae are built from amylopectin double helices, whereas the amorphous lamellae contain the branch points of the amylopectin side chains (Andreev et al. 1999, Gallant et al. 1997). Evidence has been provided that the crystalline and amorphous lamellae of the amylopectin are organized into larger, more or less spherical blocklets (Gallant et al. 1997).

The structure of starch can be studied at different levels by several techniques such as optical microscopy, scanning electron microscopy, transmission electron microscopy, and X-ray diffraction. X-ray diffraction provides information about the crystal structure of the starch polymers, but also about the relative amounts of the crystalline and amorphous phases. Cereal starches have an A-type X-ray diffraction pattern, while B-type and C-type X-ray diffraction patterns are characteristic for tuber and root starches and for legume starches, respectively. C-type starches are considered to be mixtures of A-type and B-type starches. In general, rye starches show A-type X-ray diffraction patterns, but some researchers (Gernat et al. 1993, Schierbaum et al. 1991) also reported a significant B-type portion.

Starch Physicochemical Properties

The physicochemical gelatinization, pasting, gelation, and retrogradation properties of starches are important parameters in determining the behavior of cereals in food systems.

When a starch suspension is heated above a characteristic temperature (the gelatinization temperature) in the presence of a sufficient amount of water, the starch granules undergo an order-disorder transition known as gelatinization. The phenomenon is accompanied by melting of the crystallites (loss of X-ray pattern), irreversible swelling of the granules, and solubilization of the amylose. Gelatinization can be studied by measuring the loss of birefringence of the starch granules when observed under polarized light. The end point and the range of temperatures at which gelatinization occurs can be determined. For rye starch, birefringence end point temperatures of 59.6°C (Klassen and Hill 1971) and 58.0°C (Lii and Lineback 1977) were reported. These birefringence end point temperatures were somewhat lower than those observed for wheat starches by the same authors. Another technique often used to study gelatinization-associated phenomena is differential scanning calorimetry (DSC). DSC enables determination of onset, peak, and conclusion gelatinization temperatures, gelatinization temperature ranges, and gelatinization enthalpy. The gelatinization temperature is a qualitative index of crystal structure, whereas gelatinization enthalpy is a quantitative measure of order. The DSC technique also measures the temperature and enthalpy of the dissociation of the amylose-lipid complexes. Rye starches show an onset of gelatinization at rather low temperatures. Gudmundsson and Eliasson (1991) reported onset gelatinization temperatures of 54.8–60.3°C, Radosta et al. (1992) of 53.5°C, and Verwimp et al. (2004) of 49.2–51.4°C. Rye starch has somewhat lower gelatinization temperatures and enthalpies than wheat starch (Gudmundsson and Eliasson 1991, Radosta et al. 1992, Verwimp et al. 2004). Lower dissociation enthalpies

of the amylose-lipid complexes for rye starch than for wheat starch were observed by Gudmundsson and Eliasson (1991) and Verwimp et al. (2004), indicating lower levels of lipids in rye starch.

When starch suspensions are heated beyond their gelatinization temperature, granule swelling and amylose and/or amylopectin leaching continue. Eventually, total disruption of the granules occurs, and a starch paste with viscoelastic properties is formed. This process is called pasting. Upon cooling, gelation occurs. During gelation, at sufficiently high starch concentrations (>6%, w/w), the starch paste is converted into a gel. The gel consists of an amylose matrix enriched with swollen granules. During gelation and storage of starch gels, retrogradation occurs. This is a process whereby the starch molecules begin to reassociate in an ordered structure, without regaining the original molecular order. Initially, starch retrogradation is dominated by gelation and crystallization of the amylose molecules. In a longer time frame, amylopectin molecules recrystallize. Rye starch exhibits a unique, typical swelling behavior with a high pasting temperature (79–87°C according to Schierbaum and Kettlitz 1994; 75°C according to Verwimp et al. 2004), a stable consistency during cooking, and a high viscosity increase during cooling (Schierbaum and Kettlitz 1994, Verwimp et al. 2004). It has lower pasting temperatures than wheat starch (Schierbaum and Kettlitz 1994, Verwimp et al. 2004). Fredriksson et al. (1998) and Gudmundsson and Eliasson (1991) showed that rye starches retrograde to a lesser extent than starches from wheat or corn and ascribed this to differences in the structure of the amylopectin polymers.

Nonstarch Polysaccharides

Rye contains, on average, 13.0–15.0% nonstarch polysaccharides, which serve mainly as cell wall components and the majority of which are arabinoxylans (Table 34.1). Other nonstarch polysaccharide constituents of rye are mixed-linked β-glucan, cellulose, arabinogalactan peptides, and fructans (Table 34.1). The variation in nonstarch polysaccharide content and composition is significantly influenced by both harvest year and rye genotype (Hansen et al. 2003, 2004). Most of the nonstarch polysaccharides are classified as dietary fiber because of their resistance to digestion by human digestive enzymes. In view of the major importance of arabinoxylans in rye, these components will be further discussed in detail.

Arabinoxylan Occurrence and Structure

Arabinoxylans consist of a backbone of 1,4-linked β-D-xylopyranose residues, unsubstituted or mono- or disubstituted with single α-L-arabinofuranose residues at the O-2- and/or O-3-position. To some of these arabinose residues, a ferulic acid moiety is ester bound at the O-5 position. In rye, as in other cereals, two types of arabinoxylans can be distinguished: water extractable and water unextractable. Water-unextractable arabinoxylans, representing approximately 75% of the total arabinoxylan population of the rye kernel, are unextractable because they are retained in the cell walls by covalent and noncovalent interactions among arabinoxylans and between arabinoxylans and

other cell wall constituents. Water-extractable arabinoxylans are thought to be loosely bound at the cell wall surface. Their content in the rye kernel ranges from 1.5 to 3.0% (Figueroa-Espinoza et al. 2002; Hansen et al. 2003, 2004) and is influenced by environmental and genetic factors but also by the conditions under which extraction occurs (Cyran et al. 2003, Härkönen et al. 1995). While the rye bran and shorts are high in arabinoxylan (14.9–39.5% and 13.5–18.7%, respectively), the endosperm contain lower levels (2.1–4.9%) (Fengler and Marquardt 1988a, Glitso and Bach Knudsen 1999, Härkönen et al. 1997, Nilsson et al. 1997a).

A considerable variation in substitution degree and pattern of xylose residues, arabinoxylan molecular weight, and ferulic acid content has been reported for both water-extractable and water-unextractable arabinoxylan. This variability in structure can, in part, account for the differences in extractability and solubility of the arabinoxylans.

Substitution Degree and Pattern of Xylose Residues
Bengtsson et al. (1992a) reported on what could either be two different types of polymers or two different regions in the same molecule, that is, arabinoxylan I and arabinoxylan II. Arabinoxylan I contains mainly un- and monosubstituted xylose residues with on average 50% of the xylose residues substituted at O-3 with an arabinose residue. Only 2% of the xylose residues are disubstituted at O-2 and O-3 with arabinose residues (Bengtsson and Aman 1990). The xylose residues carrying an arabinose side chain occur predominantly as isolated residues (36%) or small blocks of two residues (62%) (Aman and Bengtsson 1991). Arabinoxylan II contains mainly un- and disubstituted xylose residues with on average 60–70% of the xylose residues substituted at O-2 and O-3 with arabinose residues (Bengtsson et al. 1992a). The levels of arabinoxylan I and II in different rye varieties ranges from 1.4 to 1.7% and from 0.6 to 1.0%, respectively (Bengtsson et al. 1992b). In contrast to the two classes of arabinoxylans described by Bengtsson et al. (1992a), Vinkx et al. (1993) concluded that there were a range of rye water-extractable arabinoxylans. The latter authors fractionated rye water-extractable arabinoxylans by graded ammonium sulfate precipitation into several fractions with arabinose:xylose (A/X) ratios of 0.5–1.4, with among them a major fraction containing almost purely O-3 monosubstituted arabinoxylans and a minor fraction consisting of almost purely disubstituted arabinoxylans. All arabinoxylan fractions contained a small amount of xylose residues substituted at O-2 with arabinose (Vinkx et al. 1995a).

Cyran et al. (2003) obtained rye flour arabinoxylans with different structural features after sequential extraction with water at different temperatures. A gradual increase in the degree of substitution in general and disubstitution in particular and a decrease in O-3 monosubstitution were observed from cold to hot water-extractable fractions. Within a water-extractable fraction, subfractions obtained after ammonium sulfate precipitation showed structures analogous to those reported by Bengtsson et al. (1992a) and Vinkx et al. (1993).

Rye water-unextractable arabinoxylan molecules also consist of a range of structures, which can only be studied after alkaline solubilization of the arabinoxylans. This treatment results in the saponification of the ester bonds linking ferulic acid to

arabinose, releasing individual arabinoxylan molecules from the cell wall structure. Based on the studies of Hromadkova et al. (1987), Nilsson et al. (1996, 1999) and Vinkx et al. (1995b) (Table 34.2), three different groups of alkali-extractable arabinoxylans can be distinguished in rye bran. A first group shows an intermediate arabinose:xylose ratio (0.54–0.65) and contains mainly unsubstituted (57–64%) and monosubstituted (24–29%) xylose residues. A second group consists of almost pure unsubstituted (89%) arabinoxylans with a low arabinose:xylose ratio (0.20–0.27). A third group is characterized by a high arabinose:xylose ratio (1.08–1.10) and contains approximately 46% monosubstituted and 33% di-substituted xylose residues. In contrast to rye bran water-unextractable arabinoxylans, the rye flour alkali-solubilized arabinoxylans all show similar xylose substitution levels (Cyran et al. 2004, Vinkx 1994) (Table 34.2). However, further fractionation of the alkali-extracted arabinoxylans from rye flour by ammonium sulfate precipitation yields subfractions that differ in structure (Cyran et al. 2004). The arabinoxylans sequentially extracted with alkali from rye bran show lower degrees of branching than those extracted from rye flour by the same extraction solvent (Table 34.2).

In general, for rye bran as well as for rye flour, low yields of alkali-extractable arabinoxylan fractions with low (0.2) and high (1.1) arabinose:xylose ratios are obtained. Glitso and Bach Knudsen (1999) found lower substitution degrees for water-unextractable arabinoxylans in the aleurone layer (0.35) than for those in the starchy endosperm (0.83) and pericarp/testa fraction (1.02). From these results and because in rye milling the endosperm can be contaminated with bran, one can assume that the arabinoxylan fractions with high substitution degrees isolated from rye flour originate from contamination with bran fractions. Similarly, the arabinoxylan fractions isolated from rye bran might be contaminated with endosperm fractions.

Water-unextractable arabinoxylans in bran have a lower degree of branching than their water-extractable counterparts (Glitso and Bach Knudsen 1999), whereas the opposite is the case in the endosperm (Cyran and Cygankiewicz 2004, Glitso and Bach Knudsen 1999).

Molecular Weight Large differences in molecular weight of rye arabinoxylans exist. For rye, whole meal water-extractable arabinoxylans, average molecular weights of 770 k (Girhammar and Nair 1992a) and more than 1000 k (Härkönen et al. 1995), as determined by gel permeation chromatography, have been reported. Whether the water-extractable arabinoxylans from rye bran have a higher (Meuser et al. 1986) or lower (Härkönen et al. 1997) mean molecular weight than those from rye flour is not clear. It is also not clear whether extraction temperature affects the molecular size distribution of rye flour water-extractable arabinoxylans (Cyran et al. 2003) or not (Härkönen et al. 1995, Meuser et al. 1986). For water-extractable arabinoxylans isolated from rye varieties differing in extract viscosity, increasing molecular weights were correlated with increasing rye extract viscosity (Ragaee et al. 2001). Rye water-extractable arabinoxylans have higher average molecular weights than those of wheat (Dervilly-Pinel et al. 2001, Girhammar and Nair 1992a).

The water-unextractable arabinoxylans from rye flour have a higher molecular weight (1500–3000 k) than their

water-extractable counterparts (620–1200 k) (Meuser et al. 1986). For rye bran water-unextractable arabinoxylans, however, Vinkx et al. (1995b) found that the molecular weight of arabinoxylans solubilized with alkali were in the same range as those reported for water-extractable arabinoxylans (Vinkx et al. 1993).

Rye arabinoxylans were reported to have an extended, rodlike conformation (Anger et al. 1986, Girhammar and Nair 1992a). In contrast, Dervilly-Pinel et al. (2001) stated that the water-extractable arabinoxylans from rye have a random coil conformation.

Ferulic Acid Content   Ferulic acid residues can link adjacent arabinoxylan chains through formation of diferulic acid bridges, thereby affecting extractability of arabinoxylans.

Ferulic acid and ferulic acid dehydrodimer contents in rye vary from 0.90 to 1.17% and from 0.24 to 0.41%, respectively, and are significantly influenced by both rye genotype and harvest year (Andreasen et al. 2000b). These phenolic compounds are concentrated in the bran of the rye kernel (Andreasen et al. 2000a, Glitso and Bach Knudsen 1999).

The water-extractable arabinoxylans from rye flour contain low levels of ferulic acid (0.03–0.15%) (Figueroa-Espinoza

et al. 2002, Vinkx et al. 1993) and ferulic acid dehydrodimers (0.03×10^{-2}%) (Dervilly-Pinel et al. 2001, Figueroa-Espinoza et al. 2002).

The water-unextractable arabinoxylans from rye flour contain higher amounts of ferulic acid (0.20–0.36%) and ferulic acid dehydrodimers (0.35%) than their water-extractable counterparts (Figueroa-Espinoza et al. 2002). After alkaline extraction with saturated barium hydroxide and 1.0 M sodium hydroxide, rye flour arabinoxylans still contain a substantial level of ferulic acid. Further fractionation of these arabinoxylans by ammonium sulfate precipitation reveals increasing levels of ferulic acid with increasing ammonium sulfate concentration (Cyran et al. 2004). This observation might corroborate the above-mentioned hypothesis that the different arabinoxylan fractions with varying structures obtained from rye flour may reflect contamination of the rye flour with bran fractions.

Arabinoxylan Physicochemical Properties

Solubility of a large part of the individual arabinoxylan molecules in water is mainly associated with the presence of arabinose substituents attached to the xylose residues, which prevent intermolecular aggregation of unsubstituted xylose

residues. High molecular weight arabinoxylans with arabinose:xylose ratios below 0.3 tend to be insoluble.

Rye arabinoxylans are said to have high water-holding capacities, with water-extractable and water-unextractable arabinoxylans able to absorb 11 and 10 times their weight of water, respectively (Girhammar and Nair 1992a). These values were typically determined by addition of arabinoxylan to flour and measurement of the consecutive rise in Farinograph absorption. However, it is not clear whether the results obtained by this technique may be simply defined as "water-holding capacity." The mechanism behind water binding of discrete cell wall fragments that contain water-unextractable arabinoxylans is bound to be different from that of water-extractable arabinoxylans in solution. It is also unclear whether the increased Farinograph absorption is solely caused by the arabinoxylans. That water-holding values obtained with the Farinograph method have to be interpreted with care is clearly demonstrated by Girhammer and Nair (1992b), who reported a water-holding capacity of 0.47 g/g dry matter for rye water-extractable arabinoxylan, when determined by measuring the level of unfreezable water associated with the water-extractable arabinoxylan using differential scanning calorimetry. These authors stated that the water-holding capacity was not related to the molecular weight of the arabinoxylan. Different milling fractions of rye showed different water absorption capacities in relation to this total arabinoxylan content (Härkönen et al. 1997).

Even at relatively low concentrations, water-extractable arabinoxylans are able to form highly viscous solutions in water (Girhammar and Nair 1992b). Highly positive correlations were found between the viscosity of a rye extract and its content of water-extractable arabinoxylans (Boros et al. 1993; Fengler and Marquardt 1988a; Härkönen et al. 1995, 1997; Ragaee et al. 2001). For different rye milling fractions, extract viscosity correlates with the content of water-extractable arabinoxylans (Fengler and Marquardt 1988a, Glitso and Bach Knudsen 1999, Härkönen et al. 1997). Water extracts from rye are more viscous than those from other cereals (Boros et al. 1993, Fengler and Marquardt 1988a), which can be ascribed to the higher concentration of water-extractable arabinoxylans in rye than in other cereals. Differences in viscosity are related to differences in the structural features and molecular weight of water-extractable arabinoxylans. Although the impact of un-, mono-, and disubstitution is unclear (Bengtsson et al. 1992b, Dervilly-Pinel et al. 2001, Ragaee et al. 2001), molecular weight seems a logical determining parameter (Girhammar and Nair 1992b, Nilsson et al. 2000, Ragaee et al. 2001, Vinkx et al. 1993). Arabinoxylan conformation was also found to have a bearing on viscosity, with a higher viscosity being associated with a larger radius of gyration (Dervilly-Pinel et al. 2001, Ragaee et al. 2001). Viscosity measurement conditions such as shear rate (Bengtsson et al. 1992b, Härkönen et al. 1997, Nilsson et al. 2000) and temperature, pH, and salt concentration (Girhammar and Nair 1992b) also influence the viscosity of rye water-extractable arabinoxylan solutions.

Water-extractable arabinoxylans undergo oxidative gelation upon addition of hydrogen peroxide and peroxidase, resulting in an increase in viscosity and eventually the formation of a gel (Dervilly-Pinel et al. 2001, Vinkx et al. 1991). The phenomenon is caused by the formation of covalent linkages through oxidative coupling of ferulic acid residues esterified to arabinoxylan. The aromatic ring and not the propenoic moiety of ferulic acid is involved in the oxidative gelation (Vinkx et al. 1991). The oxidative gelation capacity of arabinoxylans depends on several parameters including the ferulic acid content, the molecular weight, and the structure of the arabinoxylans. Arabinoxylan fractions with higher ferulic acid content, higher molecular weights, and fewer disubstituted xylose residues have a higher gelation potential (Dervilly-Pinel et al. 2001, Vinkx et al. 1993). Dervilly-Pinel et al. (2001) stated that the intrinsic viscosity of arabinoxylans is the main parameter governing gel rigidity.

PROTEINS

The total protein content in rye is influenced by both environmental and genotypic factors and varies from 8.0 to 17.7% (see Table 34.1). The protein content is higher in the outer layers than in the inner layers of the rye kernel (Glitso and Bach Knudsen 1999; Nilsson et al. 1996, 1997a).

Protein Classification

Rye proteins can be separated by the classical Osborne fractionation procedure. The albumins are extractable with water, the globulins with dilute salt solutions, the prolamins with alcohol, and the glutelins with dilute acid or alkali. Chen and Bushuk (1970) found that the albumin, globulin, prolamin, and glutelin fractions accounted for 34, 11, 19, and 9%, respectively, of the total nitrogen content in a rye flour, with 21% of the protein remaining in the residue. Similar results were obtained by Preston and Woodbury (1975) and Jahn-Deesbach and Schipper (1980), except that the latter authors extracted a much higher proportion of glutelins. Gellrich et al. (2003), however, extracted fewer albumins and globulins and many more prolamins from rye flour. In all cases, rye flour contained higher levels of albumins and globulins and lower levels of prolamins and glutelins than wheat (Chen and Bushuk 1970, Gellrich et al. 2003, Jahn-Deesbach and Schipper 1980).

From a physiological point of view, rye proteins can be divided into two main groups: the storage proteins and the nonstorage proteins. The storage proteins are deposited in protein bodies in the developing starchy endosperm and function solely as a supply of amino acids for use during germination and seedling growth. They include the prolamins, glutelins, and the proteins in the Osborne residue. The nonstorage proteins include, amongst others, enzymes and (in some cases) their inhibitors and correspond with the Osborne albumin and globulin fractions.

Major differences are found in the amino acid compositions of the proteins in the two groups. The nonstorage proteins contain high proportions of lysine and arginine and low proportions of glutamine/glutamate and proline, whereas the opposite was observed for the storage proteins (Dexter and Dronzek 1975, Gellrich et al. 2003, Preston and Woodbury 1975). No significant differences exist in the amino acid composition of the proteins from different rye varieties (Dembinski and Bany 1991,

Morey and Evans 1983). The higher proportions of lysine make rye proteins nutritionally superior to wheat proteins (Chen and Bushuk 1970, Dexter and Dronzek 1975, Jahn-Deesbach and Schipper 1980, Morey and Evans 1983).

Table 34.3 gives an overview of the classification of the rye proteins, which are of technological importance and are further discussed in detail below.

Storage Proteins

Secalins The rye alcohol-soluble prolamins, also called "secalins," form the major storage proteins in rye (Gellrich et al. 2003). They have unusual amino acid compositions with high glutamine/glutamate and proline contents and low levels of basic and acidic amino acids (Dexter and Dronzek 1975, Gellrich et al. 2003, Preston and Woodbury 1975). The secalins are highly polymorphic and can be classified into three groups on the basis of their amino acid compositions: S-rich, S-poor, and high molecular weight (HMW) secalins (Fig. 34.1). Some researchers also purified secalins of low molecular weight (LMW) (10–16 k) (Charbonnier et al. 1981; Preston and Woodbury 1975), which is in the same range as that of wheat low molecular weight gliadin and barley A hordein.

The S-rich or γ-secalins are the most abundant secalins and consist of two major groups of polypeptides: 40k γ-secalins (26% of total secalin fraction) and 75k γ-secalins (45% of total

secalin fraction) (Gellrich et al. 2003, Shewry et al. 1982). The molecular weights of 40k γ- and 75k γ-secalins are 40 k and 75k, respectively, as determined by SDS-PAGE (sodium dodecyl sulfate–polyacrylamide gel electrophoresis), hence their names (Field et al. 1983, Gellrich et al. 2003, Shewry et al. 1982), and 33 k and 54 k, respectively, as determined by sedimentation equilibrium ultracentrifugation (Shewry et al. 1982) or mass spectrometry (Gellrich et al. 2001, 2003). The two groups differ in amino acid composition, with 75k γ-secalins having higher contents of glutamine/glutamate and proline and lower contents of cysteine than the 40k γ-secalins (Gellrich et al. 2003, Shewry et al. 1982, Tatham and Shewry 1991).

The γ-secalins contain two structural domains: an *N*-terminal domain rich in glutamine and proline and consisting of repetitive sequences (Gellrich et al. 2001, 2004a; Kreis et al. 1985; Shewry et al. 1982), and a *C*-terminal domain with a nonrepetitive structure, which has lower glutamine and proline content and is rich in cysteine (Kreis et al. 1985). The *N*-terminal sequences of the 40k γ- and 75k γ-secalins are identical at 16 or 17 of the first 20 positions (Gellrich et al. 2003, 2004a; Shewry et al. 1982). The *N*-terminal repetitive domains probably have a rod-like conformation (Shewry and Tatham 1990), whereas the *C*-terminal nonrepetitive domains probably have a compact globular conformation (Shewry and Tatham 1990) rich in α-helical structures (Tatham and Shewry 1991). The 75k γ-secalins have a lower content of α-helical structures than the 40k γ-secalins (Tatham

Prolamins   **Glutelins**

	$\rightarrow$	HMW prolamins	$\leftarrow$	- HMW-GS

[a]LMW-GS show strong similarities with gliadins, differing in one very important characteristic, i.e., the occurrence of interchain disulphide bonds in LMW-GS.

Figure 34.1. Schematic representation of the classification of rye and wheat proteins. LMW, low molecular weight; HMW, high molecular weight.

and Shewry 1991), consistent with a higher proportion of repetitive sequences in the former group (Shewry et al. 1982).

The two γ-secalin types differ in aggregation behavior. The 40k γ-secalins predominantly occur as monomers containing intramolecular disulphide bonds, while the 75k γ-secalins are present predominantly as disulphide-linked aggregates (Field et al. 1983, Gellrich et al. 2003, Shewry et al. 1983). A possible explanation for this different aggregation behavior is the presence or absence of cysteine residues in positions that are favorable or unfavorable for formation of intermolecular disulphide bonds. Alternatively, it might result from the specific action of enzymes responsible for the formation of such bonds (Field et al. 1983, Shewry et al. 1983). Gellrich et al. (2001, 2004b) showed that the eight-cysteine residues of the C-terminal domain of 75k γ-secalin are linked by intramolecular disulphide bonds and that the cysteine residue located in position 12 of the N-terminal domain of the 75k γ-secalin forms an intermolecular disulphide bond with 75k γ-secalins. The cysteine residue in the N-terminal domain is unique to the 75k γ-secalins and is likely to be responsible for their aggregative nature (Gellrich et al. 2003, 2004b).

The 40k γ-secalins are homologous to the wheat γ-gliadins and to the B hordeins of barley (Field et al. 1983; Gellrich et al. 2001, 2003; Shewry et al. 1982), whereas the 75k γ-secalins differ from them due to the presence of additional repetitive

sequences rich in glutamine and proline and their occurrence as aggregates. The latter are suggested to be homologous to the LMW glutenin subunits (LMW-GS) of wheat (Shewry et al. 1982) (Fig. 34.1).

The S-poor or ω-secalins are quantitatively minor components, accounting for about 19% of the total secalin fraction (Gellrich et al. 2003). They have SDS-PAGE molecular weights of about 48 k to 53 k (Field et al. 1983, Gellrich et al. 2003, Shewry et al. 1983). The amino acid compositions of the ω-secalins are characterized by high levels of glutamine/glutamate, proline, and phenylalanine and the absence of cysteine and methionine (Tatham and Shewry 1991). The ω-secalins consist almost entirely of repetitive sequences (Tatham and Shewry 1991) forming a stiff, wormlike coil (Tatham and Shewry 1995). They are present predominantly as monomers (Field et al. 1983, Gellrich et al. 2003) and are homologous to the ω-gliadins of wheat and to the C hordeins of barley (Field et al. 1983, Gellrich et al. 2003, Tatham and Shewry 1991) (Fig. 34.1).

HMW secalins are also quantitatively minor components, accounting for about 5% of the total secalin fraction (Gellrich et al. 2003). SDS-PAGE molecular weights above 100 k were observed (Field et al. 1982, Gellrich et al. 2003, Kipp et al. 1996, Shewry et al. 1983), whereas sedimentation equilibrium ultracentrifugation showed a molecular weight of 68 k (Field et al. 1982). The HMW secalins have a high content of glycine and

glutamine/glutamate and contain lower levels of proline than the other secalin groups (Field et al. 1982, Tatham and Shewry 1991). The conformation of HMW secalins has not been reported in detail, but based on studies with HMW glutenin subunits (HMW-GS) of wheat, it was suggested that they contain central repetitive sequences with a rodlike shape, flanked by nonrepetitive domains having a globular conformation rich in α-helical structure. The nonrepetitive domains contain most of the cysteine residues involved in intermolecular cross-linking (Shewry et al. 1995). The HMW secalins are present only in an aggregated state stabilized by disulphide bonds (Field et al. 1983, Gellrich et al. 2003, Shewry et al. 1983). They are homologous to the HMW-GS of wheat and the D hordeins of barley (Field et al. 1982, 1983; Gellrich et al. 2003; Shewry et al. 1982, 1988; Fig. 34.1).

Glutelins   In contrast to the wheat glutelins, which are called "glutenins," no alternative name has been given to the rye glutelin fraction. The glutelins are not soluble in aqueous alcohols. They form HMW polymers stabilized by interchain disulphide bonds. However, the individual subunits of the polymers obtained in the presence of a reducing agent are soluble in alcohol media and rich in proline and glutamine (Field et al. 1982, 1983; Gellrich et al. 2003; Kipp et al. 1996; Shewry et al. 1983). The building blocks of the glutelins are therefore considered to be secalins. The glutelins soluble in alcohol after reduction contain mainly HMW-secalins (26%) and 75k γ-secalins (52%) and small levels of 40k γ-secalins (12%) (Gellrich et al. 2003; Fig. 34.1). When the distribution of the 75k γ-, 40k γ-, ω- and HMW secalins over the storage proteins (secalins + glutelins) is considered, it can be concluded that the major portion of 75k γ-secalins is present in the prolamin fraction (40%) and only 7% in the glutelin fraction. The 40k γ-secalins (23%) and ω-secalins (16%) appear mainly in the prolamin fraction due to their monomeric state. A larger portion of HMW secalins is present in the prolamin (4%) than in the glutelin fraction (3%) (Gellrich et al. 2003).

Gluten Formation   The wheat gliadin and glutenin fractions can form a polymeric gluten network by intermolecular noncovalent interactions and disulphide bonds. In contrast to wheat, rye storage proteins do not form gluten. Despite partial homology, storage proteins of rye differ significantly from those of wheat with respect to quantitative and structural parameters that are important for the formation and properties of gluten. Typical for rye are the low content of storage proteins and the high ratio of alcohol-soluble proteins to insoluble proteins (Chen and Bushuk 1970, Gellrich et al. 2003, Preston and Woodbury 1975). The 75k γ-secalins and HMW secalins differ in aggregation behavior from the LMW-GS and HMW-GS of wheat, respectively, due to the absence (Gellrich et al. 2004b) or presence (Köhler and Wieser 2000) of cysteine residues in the C-terminal domain in positions favorable for formation of intramolecular disulphide bonds and unfavorable for formation of intermolecular disulphide bonds. It is likely that these structural differences contribute to the lack of ability of rye to form gluten. Another factor

hampering the formation of a protein network from rye secalin and glutelin fractions may be a higher degree of glycosylation in rye subunits than in wheat subunits (Kipp et al. 1996).

Functional Proteins

Among the many enzymes and structural proteins in cereals in general, the most important enzymes present in rye grain that break down its major constituents (starch, arabinoxylan, and protein) are the α-amylases, endoxylanases, and proteases, respectively. Such enzymes can be of major importance in rye processing. Rye also contains specific proteins with inhibition activity against these enzymes. Presumably, these enzyme inhibitors contribute to plant defense mechanisms and/or possibly intervene in the complex regulation of plant metabolic processes.

Starch-Degrading Enzymes and Their Inhibitors α-amylases or, in full, 1,4-α-D-glucan glucanohydrolases (E.C. 3.2.1.1) catalyze the hydrolysis of the internal 1,4-α-D-glucan linkages in starch components.

Rye synthesizes two groups of α-amylases: low pI ($\leq$ pI 5.5) and high pI ($\leq$ pI 5.8). The low-pI α-amylases are synthesized during grain development, particularly in the pericarp (Dedio et al. 1975). Their activity decreases during the later stages of grain development and is low at maturity. The high-pI α-amylases are synthesized during germination. In germinated rye, the high-pI groups represent a high proportion of the total amylase activity (MacGregor et al. 1988). Gabor et al. (1991) isolated a high-pI α-amylase from germinated rye, also called "germination-specific" α-amylase, which showed optimal activity at pH 5.5 and is stable at pH 6.0–10.0 after storage at 4°C. The temperature optimum over a 3 minute incubation period was 65°C, but 40% of the activity was lost when the enzyme was incubated without substrate for 4 hours at 55°C. Täufel et al. (1991) also isolated a germination-specific α-amylase from rye and reported a pH optimum of 5.0, pH stability between pH 5.0 and 7.0 and thermal stability up to 55°C.

Variation in α-amylase levels exists between different rye lines (Masojc and Larssonraznikiewicz 1991a). Masojc and Larssonraznikiewicz (1991b) showed the existence of low and high α-amylase genotypes. In contrast, Hansen et al. (2004) stated that the α-amylase activity is mostly influenced by harvest year, attributing only a small effect to genotype.

α-Amylase inhibitors can reduce the activity of one or more α-amylases and are mainly found in two major families, that is, the "cereal trypsin/α-amylase inhibitor" and the "Kunitz" or "α-amylase/subtilisin inhibitor" families (Garcia-Olmedo et al. 1987). The cereal trypsin/α-amylase inhibitor family represents the major part of the albumin and globulin fraction of the endosperm and consists of monofunctional inhibitors, active against either trypsin or exogenous α-amylase. The Kunitz-type inhibitors are bifunctional inhibitors of about 20 k, containing two intramolecular disulphide bridges. They can simultaneously inhibit both subtilisin and endogenous α-amylases, in particular the germination specific, high-pI α-amylase.

Täufel et al. (1991, 1997) purified two proteinaceous inhibitors of α-amylase from rye: a regulation or R-type inhibitor, which only inhibits the endogenous germination-specific α-amylase, and a defense or D-type inhibitor, which only inhibits exogenous α-amylases of animal and human origin. The inhibitors are present in different tissues of the rye kernel (Täufel et al. 1997). The R-type inhibitor predominantly occurs in the bran, whereas the D-type inhibitor is enriched in the germ and the endosperm. The high D-type inhibitor activity in these kernel sections is consistent with its assumed defense function, as it can protect the starch against exogenous α-amylases from insects and rodents. The levels of both types of inhibitor vary with growing conditions (Täufel et al. 1997). Rye varieties cultivated under drought conditions show high D-type inhibitor activities and low R-type inhibitor activities, whereas the opposite is true when they are cultivated under wet conditions. Small variations in α-amylase inhibitor activities exist between sprout-stable and sprout-sensitive rye genotypes (Täufel et al. 1997). Whereas α-amylase activity increases rapidly after 24 hours of germination, the R- and D-type inhibitor activities are stable during the 72 hours of germination (Täufel et al. 1997). The α-amylase inhibitors obviously have no importance at the early stages of growth.

Arabinoxylan-Degrading Enzymes and Their Inhibitors
Arabinoxylan structural and physicochemical properties can be impacted by enzymes such as arabinofuranosidases, xylosidases, esterases, and endoxylanases, with the latter being by far the most relevant in cereal processing.

Endoxylanases or, in full, endo-1,4-β-D-xylan xylanohydrolases(E.C. 3.2.1.8) hydrolyze internal 1,4 linkages between β-D-xylopyranose residues of (arabino-) xylan molecules, generating (arabino-) xylan fragments with lower molecular weight and (un)substituted xylooligosaccharides. Their action can thus lead to (partial) solubilization of water-unextractable arabinoxylans and to a decrease in molecular weight of water-extractable and/or solubilized arabinoxylans. The susceptibility of arabinoxylans to endoxylanase attack probably depends on their substitution degree and their substitution pattern as well as on their linkages to other cell wall components. Enzymic hydrolysis also depends on the substrate selectivity of the endoxylanases. Certain endoxylanases preferentially release high molecular weight arabinoxylans from water-unextractable arabinoxylans and slowly degrade water-extractable arabinoxylans; other endoxylanases solubilize arabinoxylans of low molecular weight and/or extensively degrade water-extractable arabinoxylans.

Based on their primary sequence and structure, endoxylanases are classified into two main groups: glycosyl hydrolase family 10 and family 11 (Henrissat 1991). Plant endoxylanases to date have been exclusively classified in glycosyl hydrolase family 10 in contrast to fungal and bacterial endoxylanases, which are present in both glycosyl hydrolase families 10 and 11 (Coutinho and Henrissat 1999).

Arabinofuranosidases (α-L-arabinofuranosidases, E.C. 3.2.1.55) hydrolyze the linkage between arabinose residues and

the xylan backbone, rendering the latter less branched and more accessible to depolymerization by endoxylanases. Ferulic acid esterase (feruloyl esterase, E.C. 3.1.1.73) can hydrolyze the ester linkage between ferulic acid and arabinose. Xylosidases (exo-1,4-β-xylosidase, E.C. 3.2.1.37) release single xylose residues from the nonreducing end of arabinoxylan fragments, thereby increasing the level of reducing end sugars. While synergy between these classes of enzymes and endoxylanases can be expected, it is not always observed (Figueroa-Espinoza et al. 2002, 2004).

Endogenous xylanolytic activity, although low, has been reported to be present in ungerminated rye (Rasmussen et al. 2001). The rye endogenous endoxylanase showed optimal activity at pH 4.5 and 40°C and was pH stable but heat labile. Xylosidase and arabinofuranosidase enzymes are also present in ungerminated rye grain (Rasmussen et al. 2001). During germination of rye, endoxylanase activity increases significantly after the first day (Autio et al. 2001).

Endoxylanase inhibitors can affect the enzymic hydrolysis of arabinoxylans by endoxylanases. Two different types of such inhibitors have been found to be present in rye (Goesaert et al. 2002, 2003).

The first type of inhibitor found in rye is the *Secale cereale* L. xylanase inhibitor (SCXI) (Goesaert et al. 2002), representing a family of isoinhibitors (SCXI I–IV) with similar structures and specificities. These inhibitors are basic proteins with isoelectric points of at least 9.0 and have highly homologous N-terminal amino acid sequences. They occur in two molecular forms, that is, a monomeric 40 k protein with at least one intramolecular disulphide bridge and, presumably following proteolytic cleaving of this form, a heterodimer consisting of two disulphide linked subunits (30 and 10 k). They specifically inhibit family 11 endoxylanases, while fungal family 10 endoxylanase is not affected (Goesaert et al. 2002). These inhibitors are homologous with wheat *Triticum aestivum* L. xylanase inhibitor I (TAXI I) (Gebruers et al. 2001).

Another family of isoinhibitors in rye, is the XIP-type (xylanase inhibiting protein) endoxylanase inhibitor family (Elliott et al. 2003, Goesaert et al. 2003). These inhibitors are basic, monomeric proteins with a molecular weight of 30 k with pI values of at least 8.5. They show inhibitory activity against fungal glycosyl hydrolase family 10 and 11 endoxylanases (Goesaert et al. 2003). Structural characteristics and inhibition specificities from the rye XIP-type inhibitors are similar to those of wheat XIP-type inhibitors (Gebruers et al. 2002).

Protein-Degrading Enzymes and Their Inhibitors Literature on proteins from different botanical sources (e.g., soy, wheat, rice) reveals that their enzymic hydrolysis can significantly alter their properties (Caldéron de la Barca et al. 2000, Popineau et al. 2002, Shih and Daigle 1997, Wu et al. 1998). This, however, has not been reported for rye protein.

Proteases hydrolyze the peptide bonds between the amino end of one amino acid residue and the carboxyl end of the adjacent amino acid residue in a protein. Endoproteases hydrolyze

peptide bonds somewhere along the protein chain, whereas exoproteases attack the ends of the protein chain and remove one amino acid at a time. The latter are called carboxypeptidases when acting from the carboxy terminus or aminopeptidases when acting from the amino terminus. Based on the chemistry of their catalytic mechanism, proteases have been classified into four groups: serine (E.C. 3.4.21), metallo- (E.C. 3.4.24), aspartic (E.C. 3.4.23), and cysteine (E.C. 3.4.22) proteases.

Nowak and Mierzwinska (1978) reported the presence of endopeptidase, carboxypeptidase, and aminopeptidase activities in the embryo and endosperm of rye seeds. Endoproteolytic, exoproteolytic, carboxypeptidase, aminopeptidase, and N-α-benzoylarginine-p-nitroanilide (BAPA) hydrolyzing activities have also been found in whole meal extracts from ungerminated rye seeds by Brijs et al. (1999). During germination, proteolytic activity increases during the first 3 days to then remain constant (Brijs et al. 2002). Milling fractions of germinated rye (Brijs et al. 2002) have much higher proteolytic activities than those of ungerminated rye (Brijs et al. 1999). The enzymes are mainly present in the bran and shorts fractions. Ungerminated rye mainly contains two classes of proteases (serine and aspartic proteases) (Brijs et al. 1999), whereas all four protease classes are present during germination (Brijs et al. 2002). Germinated rye contains mainly aspartic and cysteine protease activities; serine and metalloproteases are less abundant.

Aspartic proteases have been purified from bran of ungerminated rye (Brijs 2001). Two heterodimeric aspartic proteases were found: a larger 48 k enzyme, consisting of 32 k and 16 k subunits which are probably linked by disulphide bridges and a smaller one of 40 k, consisting of two noncovalently bound 29 k and 11 k subunits. Both proteins have isoelectric points close to pI 4.6. Rye aspartic proteases show optimal activity around pH 3.0 and 45°C and can be completely inhibited by pepstatin A (Brijs 2001). Amino acid sequence alignment showed that the rye aspartic proteases resemble those from wheat (Bleukx et al. 1998) and barley (Sarkkinen et al. 1992). Cysteine proteases were isolated from the starchy endosperm of 3-day germinated rye (Brijs 2001). SDS-PAGE revealed three protein bands with apparent molecular weights of 67 k, 43 k, and 30 k, although it was not established that all three protein bands are cysteine proteases. The rye cysteine proteases are optimally active around pH 4.0 and at 45°C and can be totally inhibited by L-transepoxysuccinyl-L leucylamido-(4-guanidino)butane (or E-64).

Protease inhibitors can reduce the activity of proteases and have also been found in rye. Boisen (1983) and Lyons et al. (1987) isolated a trypsin inhibitor from rye endosperm and rye seed, respectively. The inhibitor had a molecular weight of about 12 to 14 k, contained four disulphide bridges, and was resistant to trypsin and elastase but was completely inactivated by chymotrypsin. The amino acid composition was very similar to that of the barley and wheat trypsin inhibitors.

Mosolov and Shul'gin (1986) purified a subtilisin inhibitor from rye that belongs to the Kunitz-type inhibitor family. The inhibitor consisted of two forms with pI values of 6.8 and 7.1 and had a molecular weight of about 20 k. It inhibited subtilisin (at a molar ration of 1:1) and fungal proteinases from the genus

Aspergillus, but was inactive against trypsin, chymotrypsin, and pancreatic elastase. The amino acid composition of the rye subtilisin inhibitor was similar to that from its wheat and barley counterparts.

Hejgaard (2001) purified and characterized six serine protease inhibitors, also called "serpins," from rye grain. The serpins each have different regulatory functions based on different reactive center loop sequences, allowing for specific associations with the substrate-binding subsites of the proteases. The reactive center loops of the rye serpins were similar to those of wheat serpins. Five of the six serpins contained one or two glutamine residues at the reactive center bond, which were differently positioned than in the wheat reactive center loops. The rye serpins have a molecular weight of 43 k and inhibit proteases with chymotrypsin-like specificity, but not pancreatic elastase or proteases with trypsin-like specificity.

Protein Physicochemical Properties

The properties of rye proteins, for example, their foam-forming and emulsifying capacities, have hitherto not been studied well. Ludwig and Ludwig (1989) isolated a protein mixture from rye flour that exhibited low foam stability but excellent emulsifying properties at pH 3.5. Meuser et al. (2001) reported on a rye water-soluble protein with foam-forming capacity. It had a molecular weight of 12.3 k and an isoelectric point of 5.97. The optimum pH value for the water-soluble rye protein to form stable foam was pH 6.0. The protein did not appear to be located in specific morphological parts of the rye kernel. Wannerberger et al. (1997) found that secalins are more surface-active than gliadins. The lower molecular weight secalins spread more rapidly at the air-water interface, resulting in a higher surface pressure, than did the higher molecular weight gliadins. The surface pressure developed by both secalin and gliadin decreased with decreasing pH. Different rye milling fractions showed differences in surface behavior in relation to their protein content. The milling fraction with the highest protein content spread fastest and reached the highest surface pressure value.

RYE PROCESSING

While rye processing has gained interest because of its perceived positive health effects (Poutanen 1997), the functional properties of the rye major constituents limit the processing performance of rye in industrial processes (Weipert 1997). Milling and bread making are the most common processes in rye grain processing for human consumption.

RYE MILLING

The objective of milling is to separate the bran and the germ from the starchy endosperm and to reduce the starchy endosperm in size, in order to obtain a refined product, that is, flour. Rye milling differs somewhat from wheat milling. Rye kernels are smaller than wheat kernels, and the separation of the endosperm from the bran is poorer in rye than in wheat (Nyman et al. 1984). The extraction rate of rye flour is lower than that of wheat flour,

and at any given extraction rate, the ash content of rye flour is always higher than that of wheat flour (Weipert 1997).

Cleaning and Tempering of Rye

Prior to milling, rye grain is cleaned to remove stones, magnetic objects, broken rye kernels, cockle, oats, and ergot. Cleaning is based on a separation between rye and the impurities on the basis of size, density, and shape.

The second step involves tempering of the rye grain by adding a required quantity of moisture to bring it to an optimum condition for milling. Rye is, in most cases, milled at a moisture level of 15%, (which is 1% less than the preferred moisture level for wheat) and, in general, is tempered for a shorter time (2–4 hours with an absolute maximum of 6 hours) than wheat. This is due to the fact that water penetrates the rye kernel faster than the wheat kernel due to rye's weaker cell structure. The tempering process can be eliminated to reduce bacterial counts. However, if rye is milled too dry, the risk of shredding the bran into smaller particle sizes and thus contaminating the rye flour exists.

After tempering, a second cleaning step removes surface dirt, loose hairs, and outer bran layers. Just before milling, an additional 0.5% moisture is added (Zwingelberg and Sarkar 2001).

Milling of the Rye

In Europe, "roller" milling and "pin" milling are the most important rye milling processes. In roller milling, each passage through rolls involves particle size reduction by pressure and shear forces, followed by flour separation by particle size using sieves. Rolls are matched to the product needed. Their size, surface flutes, rotation velocity, and the gap between pairs of rolls rotating in opposite directions at dissimilar speeds, all can be selected or adjusted. Typically, milling starts with prebreak or flatting rolls, followed by six to seven break rolls, six bran finishers, and six reduction rolls. All rolls run at a differential speed of 3:1, except the flatting rolls (1:1 ratio). The first four break and reduction rolls are run dull to dull and the following breaks, sharp to sharp. A complex sieving system with plan sifters and centrifugal sifters is used. In this process, rye is fractionated into different milling streams, a number of which are combined to give the final flour. When practically all streams are used, an extraction rate of approximately 100% is reached and whole meal rye flour is obtained. When an increasing number of the fractions containing outer layer materials are left out of the reconstitution process, extraction rates decrease. For straight-run flour, a typical extraction rate is 58–68%.

In pin milling, rye is milled in impact mills, which work by the principle of impact disintegration. As this process requires a moisture content of 17–18%, rye is tempered a second time. In impact milling, five to seven milling steps are used. The extraction rate, ash content, and flour quality are similar for impact mills and roller mills. The starch damage, however, is lower in rye flour from impact mills than in that from roller mills because of the number of milling steps required.

In North America, the main objective in rye milling is to produce as much flour of the desired granulation as possible.

The ash content and color of rye flours are not as critical as for common wheat flours. Therefore, the flow sheet of a rye mill is simple relative to that of a common wheat mill. A typical rye mill contains three to five break rolls, up to two sizings, and four to six reduction rolls. All grinding rolls are corrugated and run at a differential rate of 3:1. To properly remove the bran, bran dusters precede the last two or three break passages rather than coming just at the end. Because rye flour is sticky and difficult to sift, generous sifting surfaces are required (Zwingelberg and Sarkar 2001).

Impact of Rye Constituents on Rye Milling

Rye contains higher levels of arabinoxylans than wheat (Aman et al. 1997) and is accordingly more difficult to mill. Because the arabinoxylans are hygroscopic, the flour absorbs ambient humidity and tends to clump. This interferes with sifting. For this reason, rye is milled at a lower moisture content and requires more sifting surface than wheat (Zwingelberg and Sarkar 2001).

Protein content also influences the performance of rye in the mill. When it exceeds 12%, rye becomes more difficult to grind and has a lower extraction rate (Weipert 1993a).

RYE BREAD MAKING

The bread-making behavior and performance of rye differ considerably from those of wheat (Weipert 1997). The principal reason for this is that rye proteins cannot form a gluten network, which lies at the basis of wheat bread quality. In addition, rye starch gelatinizes at a lower temperature than wheat starch and is therefore more prone to enzymic degradation during the oven phase than wheat starch. The main differences between rye and wheat breads are observed in terms of volume yield, crumb texture, and shelf life. Baking volume of rye breads is normally only about half that of wheat. However, rye bread has a longer shelf life and is richer in taste and aroma (Weipert 1997).

A wide assortment of rye-containing breads exists. They vary in size, shape, formulation, bread-making process, and sensory properties. Rye flour and whole meal rye can be incorporated into rye bread (minimum 90% rye), mixed rye/wheat bread (minimum 50% rye), or mixed wheat/rye bread (minimum 50% wheat). Other ingredients can be crushed rye grains, malted and crushed rye grains, malted rye kernels, or precooked rye kernels (Kujala 2004). Examples of rye bread types are pumpernickel (containing whole kernels), soft sourdough bread, crisp bread, rolls, and buns.

Rye Bread-Making Process

For rye bread production, acidification is a prerequisite to obtain a good quality product. The traditional method of preparing rye bread uses sourdough, although sometimes, direct acidification by lactic acid or other organic acids is used.

Preparation of Sourdough   Sourdough is classically made by mixing rye flour or whole meal rye with water, yeast, and a starter and allowing the mixture to ferment (Kariluoto et al.

2004, Meuser et al. 1994, Seibel and Brümmer 1991). As starter, a commercial culture containing lactic acid bacteria or a portion of previous sourdough, equally containing lactic acid bacteria, is used (Seibel and Brümmer 1991). In homofermentative lactic acid fermentation, the lactic acid bacteria ferment glucose mainly into lactic acid; in heterofermentative lactic acid fermentation, considerable levels of acetic acid are formed in addition to lactic acid. The formation of lactic acid and acetic acid during lactic acid fermentation can and must be controlled, as the ratio of lactic acid to acetic acid is quite important for optimal bread quality. Sourdoughs with a high lactic acid content are used mainly for rye and mixed rye breads, while sourdoughs with a high acetic acid content are ideally suited for mixed wheat bread (Seibel and Brümmer 1991). One-, two-, and three-stage sourdough processes are used (Meuser et al. 1994, Seibel and Brümmer 1991). These processes require different fermentation times, dough temperatures, and water to flour ratios, and the resulting doughs have different lactic acid to acetic acid ratios (Seibel and Brümmer 1991). Depending on the proportion of rye flour in the sourdough, various degrees of acidity are required (Seibel and Brümmer 1991).

There are different reasons for using sourdough. Acid conditions have a positive influence on the swelling of rye flour constituents and control the enzyme activity in the dough, thereby preventing early staling (Meuser et al. 1994, Seibel and Brümmer 1991). Rye flours with high enzyme activity require a higher degree of acidification than flours with less enzyme activity (Meuser et al. 1994). Bread sensory properties, such as taste and aroma, can be improved by optimal use of sourdough (Heiniö et al. 2003a, Meuser et al. 1994, Seibel and Brümmer 1991). It contributes to aroma in the bread due to the production of acids, alcohols, and other volatile compounds (Heiniö et al. 2003a, Poutanen 1997). Sourdough bread has good crumb characteristics (Seibel and Brümmer 1991) and nutritional properties (Kariluoto et al. 2004, Meuser et al. 1994, Poutanen 1997). Acidification of rye dough also protects against spoilage by mold growth, thereby improving product shelf life (Meuser et al. 1994, Poutanen 1997, Seibel and Brümmer 1991). When sourdough is used in wheat bread making, its main function is to improve sensory properties and to prolong shelf life (Brümmer and Lorenz 1991).

Mixing and Kneading   Rye flour, yeast, salt, and water are optimally mixed and kneaded with sourdough, lactic acid, or lactic and acetic acid to form a viscoelastic dough. The level of water is that yielding the required dough consistency. Rye doughs have to be mixed slowly because of their high arabinoxylan content, which leads to tough doughs when the energy input is excessive. The optimal mixing time depends on the composition and enzymic activities of the rye flour (Seibel and Weipert 2001a).

Important dough quality characteristics are dough yield, that is, the amount of optimally developed dough obtained from 100 g flour, and dough structure.

Fermentation   Mixing and kneading of the dough is followed by a floor time. Thereafter, the dough is divided into pieces, which are molded by hand into the desired shape. The doughs

are then proofed to their best potential. Fermentation takes place at 30–36°C and 70–85% relative humidity. Fermentation time depends on the composition of the flour, the activity of the flour enzymes, the dough formulation, and the fermentation temperatures.

During fermentation, carbon dioxide is produced, and the gas is retained by the dough, resulting in a volume increase of the dough. Although the rate of gas production in rye flour dough is high, the gas-retaining capacity is low, resulting in dense, compact loaves (He and Hoseney 1991).

Baking   After fermentation, the dough is placed in an oven and transformed into bread. Bread quality depends on baking temperature, uniformity of temperature in the oven, and baking time. Optimum baking temperature and time depend on the weight of the dough pieces and the shape of the loaves, which determine the rate of heat transfer. In rye bread making, at the beginning of the baking stage, steam is often used in the oven to develop good crust characteristics (Seibel and Weipert 2001a).

Important bread quality characteristics are specific volume, crumb structure, crumb elasticity, crumb firmness during storage; and sensory properties such as taste, flavor, and odor.

Impact of Rye Constituents on Dough and Bread Quality Characteristics

Different rye varieties show highly different bread-making quality as influenced by harvest year and genotype (Hansen et al. 2004, Nilsson et al. 1997b, Rattunde et al. 1994). This can be attributed to significant differences in the content and structure of the major rye constituents, which are influenced by both factors (Hansen et al. 2003).

Starch   Starch gelatinization and α-amylase activity are very important parameters for the bread-making quality of rye flour. Both properties can, for example, be measured by the falling number method or the amylograph test. The falling number is inversely related to α-amylase activity. An important parameter in the amylograph test is amylograph peak viscosity, which is correlated positively with starch content and negatively with α-amylase activity. It should be noted, however, that arabinoxylans can influence falling number and amylograph characteristics of rye flours. At similar α-amylase activity levels, higher falling numbers (Weipert 1993a, 1993b, 1994) and higher amylograph peak viscosities (Nilsson et al. 1997b) can be measured due to higher arabinoxylan contents. The arabinoxylans increase the viscosity, but also protect the starch granules against enzymic breakdown by hindering and retarding the activity of α-amylase (Weipert 1993b, 1994).

For rye bread-making suitability, a minimum starch gelatinization temperature of 63°C and, under specified experimental conditions, a minimum amylograph peak viscosity of 200 amylograph units (AU) are required. Rye shows optimal bread-making quality at a starch gelatinization temperature of 65–69°C and an amylograph peak viscosity of 400–600 AU (Weipert 1993a). Maximum bread-making quality is associated with intermediate values of falling number (Rattunde et al. 1994). Rye

flours with high α-amylase activity give a soft, sticky dough, which may be too fluid to process into bread or results in a doughlike crumb. Therefore, preharvest sprouting, which goes hand in hand with high α-amylase activity, is disadvantageous for rye flour quality. Rye flours with low α-amylase activity yield a rigid, stable dough but lead to breads of low volume having a dry and firm crumb, resulting in a short shelf life (Autio and Salmenkallio-Marttila 2001, Fabritius et al. 1997). However, when rye flours with low α-amylase activity contain high levels of total and water-extractable arabinoxylans, better dough and bread characteristics can be observed (Weipert 1993a). It is believed that optimum bread-making performance is reached at an optimal arabinoxylan to starch ratio of 1:16 (Seibel and Brümmer 1991). This ratio provides balanced water-binding capacity and water distribution in the dough and the bread crumb. A shift in favor of more arabinoxylan causes stiffening of the dough (Kühn and Grosch 1989), due to the high water-holding capacity of the arabinoxylans. It also results in breads of greater specific volume and a firmer crumb (Kühn and Grosch 1989). A shift in favor of starch results in a low dough yield, soft dough, a flat bread form, a split and tight crumb, and a low shelf life (Vinkx and Delcour 1996).

Arabinoxylans Although many studies have reported conflicting results concerning the functional role of arabinoxylans in the bread-making process and during storage of breads, they are of considerable importance for rye bread-making quality.

Rye cultivars with high total arabinoxylan content, particularly when they also have a high water-extractable arabinoxylan fraction, perform much better in bread making than those with low arabinoxylan content. This is due to the high water-holding capacity of the arabinoxylans, which results in a delay in starch gelatinization and protects starch from α-amylase degradation, resulting in a higher volume yield, a better crumb elasticity, and a longer bread shelf life (Weipert 1993a, 1994, 1997). Small differences in arabinoxylan content cause differences in water absorption and significant differences in bread-making performance (Hansen et al. 2004, Weipert 1997).

Besides the content of arabinoxylans, their structure also significantly influences rye bread-making performance. Differences in arabinoxylan structure, such as degree of branching and ferulic acid cross-linking, as well as molecular size, may have influence on water absorption (Hansen et al. 2004). A high degree of branching and a high degree of ferulic acid cross-linking of arabinoxylans are related to low water absorption in rye flour (Hansen et al. 2004).

The dough and bread-making properties of rye flour also depend on the type of arabinoxylans present. In general, dough consistency is negatively related to dough water content. Because of their high (and similar) water-holding capacities, both water-extractable and water-unextractable arabinoxylans affect dough consistency (Kühn and Grosch 1989). However, the water-extractable and -unextractable arabinoxylans affect the bread-making properties of rye flour differently. The water-extractable arabinoxylans increase bread specific volume and decrease crumb firmness, whereas the water-unextractable arabinoxylans decrease bread specific volume and form ratio and

slightly increase crumb firmness (Kühn and Grosch 1989). Increased water-extractable to water-unextractable arabinoxylan ratios result in flatter breads with higher specific volume, softer crumb, and darker crust (Cyran and Cygankiewicz 2004, Kühn and Grosch 1989).

Enzymic breakdown of the water-unextractable arabinoxylans by endoxylanases to solubilized arabinoxylans with medium to high molecular weight and with limited depolymerization of the water-extractable fraction has been reported to improve both rye (Kühn and Grosch 1988) and wheat (Courtin et al. 1999) bread-making performance. The increase in the level of high molecular weight arabinoxylans in the dough aqueous phase results in an improved water distribution and facilitation of molecular interactions between the dough constituent macromolecules. The subsequent increase in viscosity of the dough aqueous phase is likely to play a positive role in dough rheology and gas retention (Courtin et al. 1999, Rouau et al. 1994). Kühn and Grosch (1988) showed an improved crumb structure, decreased crumb firmness, increased width to height ratio, and increased loaf volume of rye bread after enzymic treatment of the water-unextractable arabinoxylans. Shelf life is also increased, resulting from an initial decrease in crumb firmness (Kühn and Grosch 1988). The endogenous arabinoxylan-degrading enzymes of rye might be active under the conditions prevailing in rye dough (Hansen et al. 2002, Rasmussen et al. 2001) and in the first part of the oven phase, thus prior to enzyme inactivation (Rasmussen et al. 2001). Endogenous enzymes in flour may thus affect crumb properties such as firmness, elasticity, and stickiness (Nilsson et al. 1997b).

According to Figueroa-Espinoza et al. (2004), the enzymic release of high molecular weight arabinoxylans may be positive due to the capacity of the latter to gel and form a polysaccharide network in the dough, thereby increasing water absorption, gas retention, bread volume, and shelf life.

Proteins Proteins are only of secondary importance for rye bread-making quality because of their inability to form a gluten network (Gellrich et al. 2003, 2004b; Kipp et al. 1996; Köhler and Wieser 2000). However, they should not be neglected, as they seem to be important at the dough-mixing step, at least for certain cultivars (Parkkonen et al. 1994). Indeed, although rye proteins do not form a regular gluten network, they have some ability to aggregate (Field et al. 1983) and are surface active (Wannerberger et al. 1997).

Sensory Properties of Rye Bread

Rye bread has a typical strong and slightly bitter flavor. The most dominant sensory attribute of rye bread is its rye-like flavor, but perceptions of sourness and saltiness are also substantially associated with rye bread (Heiniö et al. 1997). The aroma results from a mixture of many different volatile compounds formed by enzymic reactions during fermentation and thermal reactions during baking (Heiniö et al. 2003a, 2003b; Kirchhoff and Schieberle 2001). Besides the generation of aromas during these steps, the flour itself is an important source of dough aroma (Kirchhoff and Schieberle 2002). The specific rye-like flavor can be slightly modified to have a milder taste, without

decreasing the high dietary fiber content and other positive health effects of rye, for example, by using the processing techniques of sourdough fermentation, germination prior to use, and extrusion cooking (Heiniö et al. 2003a), or by milling fractionation (Heiniö et al. 2003b).

RYE IN OTHER FOOD PRODUCTS

In addition to bread, many other food products such as ginger cake, porridge, pastries, breakfeast cereals, and pasta products are based on rye (Kujala 2004, Poutanen 1997). Rye can also be fermented to produce alcoholic beverages (Seibel and Weipert 2001a).

RYE IN FEED

Although the majority of rye is fed to animals, rye is considered to be of inferior quality to other feed grains. The soluble, highly viscous rye arabinoxylans cause reductions in both the rate of digestion and the retention of nutrients in the gastrointestinal tract (Boros et al. 2002, Fengler and Marquardt 1988b). Therefore, rye is generally used in small proportions in mixtures with other grains. The use of enzymes (Boros and Bedford 1999, Boros et al. 2002, He et al. 2003, Lazaro et al. 2003), however, has recently substantially increased the proportion of rye included in animal feed.

RYE FRACTIONATION

Wheat is an important raw material in the industrial separation of gluten and starch because of the abundant applications for gluten and starch in both the food and nonfood sectors. Rye would be an interesting alternative raw material because of the specific properties of the rye constituents. However, in spite of the development of some methods on the laboratory scale to separate starch from the arabinoxylans and proteins in rye (Schierbaum et al. 1991), no such industrial process exists for rye, presumably because of its relatively high content of arabinoxylans with high water-holding capacity and the inability of the rye proteins to form gluten.

RYE IN INDUSTRIAL USES

Rye and rye products are also used in industrial applications such as production of adhesives and glue, film coating, sludge and oil-well drilling materials, and textiles and paper (Seibel and Weipert 2001b).

RYE AND NUTRITION

Rye products, especially when they contain whole meal rye flour, provide considerable levels of dietary fiber, vitamins, minerals, and phytoestrogens, all of which are considered to have positive health effects (Poutanen 1997). High rye consumption leads to positive effects on digestion and decreased risk of heart disease, hypercholesterolemia, obesity, and non-inulin-dependent diabetes (Hallmans et al. 2003, Smith et al. 2003). It proba-

bly also protects against some hormone-dependent cancer types (Hallmans et al. 2003, Smith et al. 2003). Liukkonen et al. (2003) showed that many of the bioactive compounds in whole meal rye are stable during processing and that their levels can even be increased through suitable processing (e.g., sourdough bread making). Rye milling, however, is accompanied by losses in dietary fiber and other phytochemicals, since these compounds are concentrated in the outer layers of the rye kernel (Glitso and Bach Knudsen 1999, Liukkonen et al. 2003, Nilsson et al. 1997a). In overall nutritional value, rye has some advantages over wheat because of the higher content of dietary fiber, vitamins, minerals, phytoestrogens, and lysine in rye.

Part 6
Health/Functional Foods

35
Biochemistry and Probiotics

Claude P. Champagne and Fatemeh Zare

Abstract: The level of viable cells is essential to the functionality of probiotic bacteria in foods. Many enzymatic activities have been identified to be critical in the ability of probiotics cultures to grow in food matrices, remain stable during storage, survive passage to the stomach and duodenum as well as to express activity in the gastro-intestinal tract (GIT). The importance of the following enzymatic activities on these functionalities will be addressed: α-galactosidase for growth in soy and pulses as well as to help prevent gas discomforts in the GIT, β-galactosidase for growth in milk as well as to reduce lactose maldigestion problems in the GIT, proteases for growth in milk and soy as well as to generate bioactive peptides, oxidases and peroxidase to prevent oxygen toxicity during fermentation and storage, proton-translocating ATPases for survival to acid environments in foods and the GIT, bile salt hydrolase for survival in the GIT and bioactivity toward cholesterol metabolism, β-glucosidases for the release of bioactives (isoflavones, quercetin) during fermentation.

INTRODUCTION

Probiotics are live microorganisms which, when administered in sufficient quantity, confer a health benefit to the host (Araya et al. 2002). Many health effects have been suggested: improved carbohydrate digestion in the gastrointestinal (GI) tract, reduction of the incidence of diarrhoea, immune system enhancement, blood cholesterol reduction (Shah 2000, Farnworth 2004). Official recognition of these effects by regulatory agencies is beginning (EFSA 2010). In light of these potential health benefits, digestive health is considered as one of the ten key food trends for 2010 (Mellentin 2010). As a result, the market for foods which contain probiotic bacteria is in constant increase and is predicted to reach US$30 billion by 2015 (Starling 2010).

From a technological and biochemical standpoint, this definition of probiotics implies two important features: (1) the cells must be viable, and (2) a certain quantity must be maintained. However, data suggest that, for some applications, non-viable cells can present biological activity as well (Ouwehand and Salminen 1998). The benefits of probiotics are increasingly linked to specific biogenic metabolites (Stanton et al. 2005) that may not necessarily require viable cells. In the current definition of probiotics, fermented foods that carry bioactive compounds but do not have viable cells are not considered to be as probiotics. If the functionality of the product is nevertheless directly linked to some activity of the probiotic culture, then the concept of "probioactive" may better apply to this health function. It has been proposed that a probioactive be "a bioactive compound influencing health that is synthesized by a probiotic culture or that specifically results from the bioconversion of a food matrix by a probiotic microorganism" (Farnworth and Champagne 2010). Exopolysaccharides, peptides, deconjugated metabolites

(e.g., isoflavones), and enzymes are but a few of the many compounds have been suggested as being linked to functionality of probiotics. In this chapter, the potential contribution of enzymes produced by probiotic bacteria to their functionality will be examined. The critical contribution of enzymes will be addressed from both a technological perspective (ability to grow and remain viable in a food product) and a health perspective (survival to GI environments, effects on human functions).

BIOCHEMISTRY AND GROWTH OF PROBIOTIC CULTURES IN FOODS

Several different metabolic pathways explain the biosynthetic functions of microorganisms that could maintain their life. Each metabolic pathway consists of many reactions that are regulated by different enzyme systems, and so the level of enzymes and their activity sustain and control the functions of the microbial cell (Stanier et al. 1987). Breakdown of nutrients (carbohydrates, proteins, lipids, and other minor constituents) present in the growth medium results in the production of smaller molecules that are subsequently consumed for buildup and division of the microbial cells as well as energy requirements for survival.

In lactic acid bacteria (LAB) (i.e., the lactococci, leuconostoc, lactobacilli, streptococci, and bifidobacteria), energy is mainly supplied by the fermentation of carbohydrates (Lawrence et al. 1976). Hundreds of enzymes are required to sustain life in microorganisms. However, some are recognized as being more critical in affecting growth rates and biomass levels on food substrates. In general, the two most important biochemical reactions are carbohydrate assimilation and protein metabolism. This justifies the focus that will be made of these particular enzymatic activities.

MILK

In milk, "lactase" and "protease" activities of yogurt and probiotic cultures are critical to growth and acidification rates (Tamime and Robinson 1999).

Lactose is the main carbohydrate in milk and it can be metabolized either through the homo- or heterofermentative metabolic pathways. *Streptococcus thermophilus, Lactobacillus delbrueckii subsp. bulgaricus*, and *Lactobacillus acidophilus* ferment lactose homofermentatively, lactic acid being the main metabolite. *Bifidobacterium* spp., on the other hand, ferments the same sugar heterofermentatively, producing lactic and acetic acid typically at a 2:3 ratio. Lactose must enter the cytoplasm to be catabolized. A specific system is involved in lactose transport in the lactococci and certain strains of *L. acidophilus* and sugar is phosphorylated by phosphoenolpyruvate (PEP) during translocation by the PEP dependent phosphotransferase system (PTS) (Kanatani and Oshimura 1994, Marshall and Tamime 1997). This mechanism is known as PEP:PTS. β-Phosphogalactosidase hydrolyses lactose-6-phosphate to its monosaccharide components. The galactose and glucose thus released are then catabolized via Tagatose and Emden–Meyerhof–Parnas (EMP) pathways, respectively (Monnet et al. 1996, Marshall and Tamime 1997). Some organisms including *Bifidobacterium* spp. have an

alternative system for lactose transport into the cells that involves cytoplasmic proteins (permeases). This is to translocate lactose without chemical modification and the mechanism could be similar to the lactose permease system in *Escherichia coli*. After lactose enters the cell, it is hydrolyzed by β-galactosidase (β-gal) to nonphosphorylated glucose and galactose. In many yogurt cultures, glucose is catabolized to pyruvate and the galactose is secreted from the cell. Less is known on the lactases of probiotic bacteria. Some bifidobacteria seem to have two types of β-gal and their level seem critical to rapid growth in milk. Indeed, Desjardins et al. (1991) showed that the growth performance of bifidobacteria in milk is linked to their β-gal levels. *L. acidophilus* or *Bifidobacterium* sp. generally grows faster on synthetic media than on milk (Misra and Kuila 1991, Gaudreau et al. 2005). Therefore, it is not surprising that the addition of β-gal to milk enhances the growth rate of *L. acidophilus* (Khattab et al. 1986). In an interesting variation of this concept, ruptured cells of a yogurt culture were added to milk in order to promote the development of *L. acidophilus* and *Bifidobacterium longum* in the fermented product (Shah et al. 1997). Presumably, the liberation of β-gal from the ruptured starter cells contributed to the stimulation. This was also noted for *Lactobacillus rhamnosus* (Gaudreau et al. 2005). However, the ability of a strain to synthesize enzymes essential in the assimilation of a carbohydrate provides an incomplete picture of the ability to grow rapidly on the food matrix. The activity of the enzymes will also influence growth rates. Thus, for a given strain, growth rates in identical media will vary as a function of the carbohydrate (Table 35.1). There are numerous observations of variable enzyme activity levels between strains (Desjardins et al. 1991, Donkor et al. 2007).

The protein fraction in milk is composed of casein and whey proteins and the basic constituents of a protein molecule are compounds from 21 amino acids (Tamime and Robinson 1999). Since LAB cannot synthesize many amino acids (Marshall and Law 1984), proteolytic activity is greatly involved in both nutrition and interactions between the two yogurt cultures as well as with probiotic bacteria. Amino acids and peptones are good supplements for bifidobacteria (Klaver et al. 1993). This would suggest that high proteolytic activities would enhance growth rates and levels. This is not always the limiting factor with

Table 35.1. Effect of the Nature of the Sugar on Growth Rate (h^{-1}) of Two Probiotic Cultures in a Laboratory Growth Medium (Peptones, Salts, Tween)

Carbohydrate	*Lactobacillus helveticus* R0052	*Bifidobacterium longum* R0175

bifidobacteria (Desjardins et al. 1991). Indeed, some *L. acidophilus* and *Bifidobacterium* cultures have proteolytic activities as high as those of yogurt starters (Shihata and Shah 2000), but still do not multiply as fast in milk. In some instances, mixing a nonproteolytic *Bifidobacterium* strain with a highly proteolytic *L. acidophilus* culture will be helpful (Klaver et al. 1993), but if the LAB grows too fast the fermentation time is shortened and counts in probiotic bacteria can even be lowered (Shihata and Shah 2002).

Proteolytic activities are not only crucial for the development of pure cultures, but also they are also crucial in a symbiotic relationship between the two strains that compose the yogurt cultures. As for probiotics, yogurt starters require an exogenous nitrogen source and utilize peptides and proteins in their growth medium (milk) by more or less complete enzyme systems. Besides the free amino acids, the enzymatic hydrolysis of milk proteins results in the liberation of peptides of varying sizes and soluble nitrogenous compounds. In yogurt, peptides, free amino acid and other released components depends on the type of milk (animal species, season), type of proteolytic enzyme and bacterial strains, heat treatment, manufacturing techniques, and storage conditions (Zourari et al. 1992, Tamime and Robinson 1999). In yogurt, *L. bulgaricus* is the main species responsible for increasing free amino acid (Zourari et al. 1992, El-zahar et al. 2004) that partially explains the associative growth relationship that exists between *S. thermophilus* and *L. bulgaricus*. Therefore, the proteinase activity of *L. bulgaricus* hydrolyzes the casein to yield polypeptides, which are broken down by the peptidases of *S. thermophilus* with the liberation of amino acids (Tamime and Robinson 1999). The proteinase of *L. bulgaricus* is more active on β-casein than on whey proteins (Zourari et al. 1992) and has an optimum pH between 5.2 and 5.8 (Argyle et al. 1976, Ezzat et al. 1987). The importance of peptides for their growth stimulation and their acidification is now well established, especially for *S. thermophilus* (Zourari et al. 1992). According to Accolas et al. (1971), the stimulation of *S. thermophilus* by milk culture filtrate of *L. bulgaricus* was due to the presence of valine, leucine, isoleucine, and histidine. Bracquart et al. (1978) as well as Bracquart and Lorient (1979) reported that reducing the growth medium of valine, histidine, glutamic acid, tryptophan, leucine, and isoleucine results in reduction in stimulation of *S. thermophilus* to 50% (Tamime and Robinson 1999).

SOY AND PULSES

Soy beverages contain, by order of importance, sucrose, stachyose, raffinose, glucose, and fructose. Therefore, to grow in milk, the ability to use lactose is critical, but cultures have a variety of options in soy substrates. The assimilation of sucrose requires invertase, while the hydrolysis of stachyose and raffinose demands α-galactosidase (α-gal). In soy substrates, the lactobacilli and the streptococci mainly use sucrose, glucose, and fructose, while the bifidobacteria tend to use stachyose and raffinose (Champagne et al. 2009). However, the ability of probiotic bacteria to synthesize these enzymes varies much between strains and *L. acidophilus*, as well as yogurt starter cultures may possess α-gal (Donkor et al. 2007). Therefore, strain selection must be carried out (Champagne et al. 2009). The α-gal of *B. longum* has an optimal activity at pH 5.8 and between 40–45°C (Garro et al. 1994). In soy, numerous enzymatic substrates are required to assimilate all carbohydrates. Thus, α-gal will hydrolyze stachyose and then raffinose to generate galactose and sucrose (Connes et al. 2004). Invertase is then required for sucrose hydrolysis. Therefore, complete assimilation of the soy carbohydrates requires two sets of hydrolytic enzymes. Thereafter, it is the ability to assimilate the monosaccharides that modulates growth rates. Not all probiotic cultures can metabolize the products of α-gal and invertase (galactose, glucose, and fructose) (Table 35.2), and even then, growth rates vary (Table 35.1).

It was observed that *B. longum* R0175 acidified milk at a much slower rate than *Lactobacillus helveticus* R052 (Fig. 35.1), and that the bifidobacteria grew at half the rate *of L. helveticus* on lactose (Table 35.1). These data suggest that acidification rates of milk by two probiotic bacteria (Fig. 35.1) can potentially

be linked to their growth rates on lactose (Table 35.1). It was examined, if this extended to soy fermentation as well. However, it was observed that acidification rates in a soy beverage by two probiotic cultures were much higher than in milk (Fig. 35.1) even though their growth rates on soy carbohydrates were lower that on lactose (Table 35.1). These data show that enzyme activity on carbohydrate is not always the limiting factor on growth rates and fermentative activity. As was the case in milk, amino acids in soy

are mainly found in the proteins. Therefore, proteolytic activities are crucial to attain high biomass levels in a soy substrate. A link was indeed established between the ability of bifidobacteria to synthesize galactosidases as well as proteinases and their multiplication in a soy substrate (Donkor et al. 2007).

With respect to soy, another enzymatic system is also of interest: hexanal and pentanal assimilation. These compounds contribute to the "beany" flavor of soy (Desai et al. 2002, Blagden and Gilliland 2005). For some consumers, this is an undesirable trait. Both lactobacilli (Blagden and Gilliland 2005) and bifidobacteria (Desai et al. 2002) have been shown to reduce the level of these metabolites in fermented soy products.

PREBIOTICS AND OTHER FOODS

Prebiotics are nondigestible food ingredients that beneficially affect the host by selectively stimulating the growth and/or activity of one or a limited number of bacteria in the GI system, and thereby confer health benefits to the host (Roberfroid 2007). This definition overlaps with the definition of dietary fiber, with the exception of its selectivity for certain bacterial species and a wider range of health effects. Peptides, proteins, and lipids contain prebiotics characteristics, but some carbohydrates have received the most attention, including lactulose, inulin, and a range of oligosaccharides that supply a source of fermentable carbohydrate for the beneficial bacteria in the colon (Prado et al. 2008).

The nutritional composition of pulses such as complex carbohydrates (Table 35.3), protein, vitamins, and minerals as well as antioxidants, and only very small amounts of unsaturated

[a]Not defined.
From Wang and Daun, 2004.

fats made this ingredients as a very good source of prebiotic components for human body as well as yogurt and probiotics bacteria (Boye et al. 2010). Enriching milk with prebiotic supplements (Capela et al. 2006) enhances the stability of probiotics in yogurt, but very few studies have been conducted with soy or pulses. Addition of soy protein isolates in yogurt does not improve stability during storage (Pham and Shah 2009) but some pulses do (Zare et al. 2011).

Food fermentations with probiotics have mainly been conducted on dairy and soy substrates. Pulses contain many of the carbohydrates of soy but there are also various other oligosaccharides (Table 35.3). Therefore, from a carbohydrate perspective, growth of probiotics in pulses should require similar enzymatic profiles to those required in soy; however, a wider range of cultures can theoretically develop in some pulses due to the presence of verbascose or other oligosaccharides.

Cereal-based products also offer many possibilities for the development of probiotic-based (Farnworth 2004). Cereals mainly have starch. Assimilation of starch typically requires amylases and maltases.

Vegetables are also frequently used as substrates for lactic acid fermentations and are thus potential matrices for probiotic cultures (Farnworth 2004). Sucrose is often found in these matrices, but a wide variety of substrates are encountered. In celery, for example, mannitol is the main carbon-based substrate but original polysaccharides are also discovered (Thimm et al. 2002).

It would take too long to examine each plant-based matrix for the required enzymes. Following are the points that must be emphasized:

1. Carbohydrate substrates vary as a function of the food matrix (Table 35.3) and, thus enzymatic requirements vary accordingly.
2. There is variability in the ability of probiotic bacteria to use the carbohydrates (Tables 35.1 and 35.2); a strain selection process is required.

BIOCHEMISTRY AND STABILITY DURING STORAGE IN FOODS

Protection Against Oxygen

Probiotic bacteria are sensitive to many processes (heating, freezing, aeration) associated with food production or storage conditions (Champagne et al. 2005). But they are also sensitive to some conditions that occur during storage. The two most important are the presence of oxygen and high acidity of the food. In both cases, some enzymatic systems may enhance the survival of the cultures to these stressful conditions.

Since the intestines offer an anaerobic environment, many strains are not adapted to growth in aerobic conditions. Technological adaptations can be made: microencapsulation, addition of antioxidants, packaging conditions (Talwalkar and Kailasapathy 2004, Jimenez et al. 2008). But some strains do possess enzymatic systems that enhance their stability in foods containing oxygen. The major problem associated with the presence of oxygen is that hydrogen peroxide is produced in various metabolic pathways. The two major enzyme systems that eliminate this toxic by-product of oxygen are NADH oxidase and NADH peroxidase (Shimamura et al. 1992, Talwalkar and Kailasapathy 2003). These systems are inducible. Thus, when cultures are gradually exposed to peroxide, an increased synthesis of these enzymes occurs. NADH oxidase and NADH peroxidase function optimally at pH 5.0 (Talwalkar and Kailasapathy 2003), which suggests that the protection to oxygen would be higher in acid foods (yogurt, fruit juices) than in neutral foods (unfermented milk, vegetables). Not surprisingly, it was shown that when a probiotic culture was added at the beginning of a yogurt fermentation process, it was more stable during storage than when it was added directly during the finished product (Hull et al. 1984). One hypothesis was that the cultures were gradually exposed to H_2O_2 produced by *L. delbrueckii* ssp. *bulgaricus* during fermentation and that enzymes were synthesized that were subsequently useful during storage. Indeed, when catalase was added in the products having direct inoculation of the probiotic culture in the finished product, an increased stability during storage was noted, while this was not the case in those where the probiotic culture was added earlier in the manufacture (Hull et al. 1984). It can also be argued that the gradual exposure to acid during fermentation would also be involved in the beneficial effect of inoculation at the beginning of the fermentation. Thus, enzymatic adaptation in acid environments needs to be addressed.

Protection Against Acid

Most LAB and probiotic cultures have optimum growth rates between pH 5.5 and 6.6. Consequently, when they are exposed for short or long periods to pH levels below 5.5 (cheese, yogurt, fruit juices, stomach) acid diffuses into the cells and reduces the efficiency of the enzymatic processes. Death may ultimately result. Indeed, numerous studies report high viability loses of probiotics exposed to the acid of the stomach (Mainville et al. 2005) as well as during storage in acid foods (Champagne et al. 2005). In the latter situation, there is often a correlation between the poststorage pH in yogurts and the survival of probiotic bacteria (Kailasapathy et al. 2008).

It is well known that LAB try to maintain an intracellular pH (pH_i) constant in these acid environments, but it is not always possible. As a result, pH_i may drop and generate a variety of responses (O'Sullivan and Condon 1997). In many cases, an acid tolerance response (ATR) occurs that significantly increases the ability of cells to survive a short exposure (a few hours) to high acid environments. In addition, cross-protection occurs and ATR helps protect against short-term stresses caused by heating, H_2O_2, salt, and ethanol (O'Sullivan and Condon 1997). The effect of the matrix medium on pH_i varies between strains and if affected by incubation time (Nannen and Hutkins 1991). Therefore, ATR is not generalized amongst the LAB. Unfortunately, most ATR studies were tested on short exposures to acidity, such as passage through the GI tract, but little is known on the enzymatic factors that will improve stability to weeks of exposure to acid. There seems to be a statistically significant correlation between stability during storage in a fruit drink and the ability of the strains to grow at pH 4.2, but that the relationship was not

strong ($R^2 = 0.49$) (Champagne and Gardner 2008). More data are needed for the enzymatic activities associated with resistance to long-term exposure to acid foods.

BIOCHEMISTRY AND HEALTH FUNCTIONALITY

SURVIVAL TO GASTRIC ACIDITY

Many bacteria do not survive passage to the conditions of the GI tract and, as mentioned previously, one of the most important criteria for functionality of probiotic bacteria is the survival to acid conditions of the stomach (Prasad et al. 1998, Mainville et al. 2005).

Proton-translocating ATPases are the enzymes that are principally involved in maintaining a high pH_i, as they contribute to excrete protons outside the cell (De Angelis and Gobbetti 2004). There are other enzymatic systems as well. The arginine deiminase pathway, which involves three enzymes, contributes to maintaining pH_i by producing ammonia as well as ATP for the ATPases (De Angelis and Gobbetti 2004). It must be kept in mind that there must be a source of ATP for the proton-translocating enzymes to function. Therefore, acid resistance of probiotic cells in the stomach can also be linked to the presence of a fermentable sugar in the medium (Corcoran et al. 2005). This shows that numerous enzymatic systems interact to prevent a big drop in pH_i, when the bacteria produce lactic acid during their fermentation or when the cells are exposed to an exocellular environment having a low pH.

As mentioned previously, cells can be adapted to enhance their resistance to acid. This ATR has been shown to be effective on subsequent short-term acid stresses such as those that occur when cells are exposed to gastric solutions. As a result, enzymatic adaptations (H^+-ATPases or others) improve the survival of probiotics to passage in the GI tract (Matto et al. 2006).

In summary, it can be assumed that survival of probiotics to passage in the stomach requires at least two sets of enzymes: (1) those that can assimilate sugar or amino acid substrates and generate ATP and (2) those that excrete protons outside the cell to help maintain an acceptable pH_i.

LACTOSE MALDIGESTION

Lactase insufficiency indicates that the concentration of the β-gal in the cells of the small intestine mucosa is very low. As a result, hypolactasia causes insufficient digestion of lactose in the GI tract. This phenomenon is alternatively called lactose malabsorption, lactose maldigestion, or lactose intolerance by various authors. In addition to the intrinsic intestinal lactase activity and its determinants, other parameters that affect lactose digestion include ethnic origin and age. Lactase activity is high at birth, decreases in childhood and adolescence, and remains low in adulthood. The symptoms of lactose intolerance are increased breath hydrogen, flatulence, abdominal pain, and diarrhoea.

An official recognition of the benefit of yogurt in lactose digestion in the GI tract has been granted (EFSA 2010) and evidence points toward a reduction of symptoms of intolerance in lactose maldigesters. The synthesis of β-gal by the yogurt starter culture is considered as the probioactive component involved in the positive effects on intestinal functions and colonic microflora, and reduced sensitivity to symptoms. Unbroken bacterial cell walls act as a mechanical protection of lactase during gastric transit and also affect the discharge of the enzyme into the small intestine; they consequently influence the efficiency of the system. It must also be mentioned that reduced amounts of lactose are often found in cheeses due to lactose utilization by starter microorganisms (Kilara and Shahani 1975, De Vrese et al. 2001).

Lactose catabolism mainly occurs by β-gal derived from the yogurt starters in fermented milk processing. The optimum activity of streptococcal β-gal is at a neutral pH and at 55°C in presence of buffer. Activity of β-gal is stimulated in presence of Mg^{2+} and oxgall (0.15 mL/100mL), while ethylenediaminetetraacetic acid (EDTA) causes inhibition. Thermal denaturation occurs at 60°C, although stability can be enhanced by the addition of bovine serum albumin (Chang and Mahoney 1994). Therefore, it can be expected that yogurt drinks heated at high temperatures to enable storage at room temperature would not contain active β-gal and therefore not present the enzymatic functionality.

In comparison with yogurt cultures, other probiotic bacteria usually promote lactose digestion in the small intestine less efficiently. However, it is suggested that some probiotic bacteria may act by preventing symptoms of intolerance in the large intestine in addition to (or rather than) by improving lactose digestion in the small intestine (De Vrese et al. 2001). It is noteworthy that yogurt cultures are generally not included in lists of probiotic bacteria (Stanton et al. 2003, CFIA 2009), presumably because they generally do highly survive the gastric transit nor grow in the intestines, but some authors do consider them as candidates (Santosa et al. 2008).

BLOOD CHOLESTEROL LEVEL

High cholesterol in serum is associated with the incidence of human cardiovascular diseases (Othman et al. 2011). One of the health-promoting benefits of probiotics is their ability to reduce blood cholesterol, which was observed in humans (Xiao et al. 2003) and animals (Du Toit et al. 1998, Nguyen et al. 2007). However, some studies have been negative (Simons et al. 2006). This points to a specific biological activity that is variable between cultures. Bile salt hydrolase (BSH) in probiotics renders them more tolerant to bile salts, and it is believed that this activity also helps to reduce the blood cholesterol level of the host (Taranto et al. 1997). Indeed, oral administration of encapsulated BSH reduced serum cholesterol levels in mice by 58% (Sridevi et al. 2009). It is thought that bile salt deconjugation affects its enterohepatic circulation (Kim and Lee 2008), but the BSH hypothesis has not yet been completely demonstrated or elucidated.

Three different types of BSH from various *Bifidobacterium* strains have been identified (Kim et al. 2004, Kim and Lee 2008). Data show that higher BSH activity can be acquired (Noriega

et al. 2006). It is unknown if cells that are suddenly exposed to bile salts upon entrance to the duodenum can increase their BSH level and increase their functionality. Thus, BSH activity in the GI tract can potentially be enhanced by culture preparation methodologies prior to consumption.

It must be kept in mind, however, that the production of secondary deconjugated bile salts through BSH activity may have undesirable effects. Contradictory data suggest that colon cancer could be enhanced (Patel et al. 2010), while another study suggests that *Lactobacillus reuteri* could have protective properties through precipitation of the deconjugated bile salts and a physical binding of bile salts by the bacterium, thereby making the harmful bile salts less bioavailable (De Boever et al. 2000). Therefore, more data are needed to better ascertain the desirability of BSH activity.

Gas Discomforts

It is considered that oligosaccharides that are not broken down by the human GI enzymes may be responsible for gas production in the GI tract (Yamaguishi et al. 2009). Since they are not assimilated in the small intestine, these oligosaccharides end up in the colon where they are fermented by the microbiota (LeBlanc et al. 2008). Unfortunately, the consumption of beans has been associated with gas production in the GI tract (Machaiah et al. 1999) if consumed in sufficient amount. Fortunately, symptoms reduce on frequent and continuous consumption (O'Donnell and Fleming 1984), but means to reduce discomforts are nevertheless desirable.

Legumes can be good substrates for the growth of probiotics (Chopra and Prasad 1990), but strain selection is required (Farnworth et al. 2007). Although some probiotic cultures only use the short-chain carbohydrates in legumes (Desai et al. 2002), the prospect of introducing probiotics into a high-fiber bean product is a very promising one. It is unknown at the present time, if the carbohydrates in beans can indeed have a positive impact on survival and growth in the GI tract. In addition to the health benefits, probiotics may also have the potential of reducing problems associated with digestibility.

Various studies in animals (LeBlanc et al. 2008) and in humans (Nobaek et al. 2000, Di Stefano et al. 2004) have shown the potential of probiotics to reduce the symptoms of gas discomforts. There appears to be a link between the synthesis of α-gal, which hydrolyze the oligosaccharides in beans, and the bioactivity of the cultures (LeBlanc et al. 2008). As a result, a product (Proviva Fruit Drink) has received an opinion by the Swedish Nutrition Foundation (SNF 2003) "that an effect to decrease flatulence is reasonably well documented." This was apparently the first such specific health benefit recognition for probiotic bacteria. The culture used was *Lactobacillus plantarum* 299v. However, a similar petition with *L. rhamnosus* GG was not granted (EFSA 2008).

This benefit of probiotics on sugar metabolism in the GI tract through α-gal resembles that of β-gal for lactose maldigestion mentioned previously. It is unknown to what extent live cells are required for the health benefit to occur.

Other Benefits

For probiotic bacteria, the main purpose of proteases is for nutrition. By hydrolysing proteins in the medium, the cells gain access to peptides and amino acids for the synthesis of their own proteins. However, there are instances where peptides show biological activities. Milk caseins have particularly been assessed in this respect (Korhonen and Pihlanto 2006). Thus, milk proteins contain peptidic angiotensin I-converting enzyme (ACE) inhibitors, which can be released by proteolysis during milk fermentation by some strains of *L. helveticus* (Leclerc et al. 2002). Hydrolysis of soy proteins by probiotic lactobacilli has also revealed the presence of ACE inhibitors (Donkor et al. 2005). Through the ACE inhibition, peptides exert antihypertensive activity. It is important to stress that the functionality of probiotics is linked to the substrate on which growth has occurred. That is why the concept of probioactive not only includes bioactive compounds synthesized by the probiotic cells as such, such as exopolysaccharides, but also includes probioactives that are specifically the result of transformation of the food substrate. This link between probiotic functionality and the food matrix may partially explain why there are contradictory data on the benefits of probiotics in the literature. An ACE inhibition activity recorded in fermented milk may unfortunately not extend to fermented fruits or vegetables low in proteins.

The production of peptides is not the only way lactic cultures can affect blood pressure. Certain strains of *Lactococcus lactis* convert glutamic acid to gamma-amino butyric acid (GABA) thanks to glutamate decarboxylase (Inoue et al. 2003, Minervini et al. 2009). High levels of free glutamate are rarely found in foods, and proteolysis is generally required to release glutamate from proteins before GABA production can occur. The activity of glutamate decarboxylase tends to be higher in acid environments (Komatsuzaki et al. 2005). Therefore, fermented milk or soy beverages seem particularly well suited for GABA production.

Foods naturally contain antioxidants and bioactive compounds, but some are linked to sugars or proteins. When combined with sugars or other food ingredients, some of these bioactive compounds have less biological activity. Therefore, deconjugation of the bioactives and their release into the product are desirable. Two examples serve to illustrate this particular concept: (1) isoflavones in soy and (2) quercetin in onions.

Antioxidants are bioactive compounds that are quite varied in chemical. In foods, examples include carotenoids, terpenes, anthocyanins, isoflavones, and flavonoids like quercetin. Quercetin is of interest because of its high antioxidant capacity, that is, 229% higher than that of ascorbic acid (Kim and Lee 2004). In onions, quercetin is mainly found in three forms: (1) quercetin diglucoside (Qdg), (2) quercetin monoglucoside (Qmg), and (3) free quercetin. Fermentation of red onions by lactic cultures substantially increased the proportion of Qmg (Bisakowski et al. 2007), that may have a positive effect as fractions containing higher ratios of Qmg:Qdg have been reported to have higher antioxidant activity (Makris and Rossiter 2001). The enzymes responsible for this useful bioconversion in onions are glucosidases. These enzymes contribute to enhancing the biological

Table 35.4. Some Enzymatic Activities Which May be Linked to the Functionality of Probiotic Bacteria

Enzyme	Function	Functionality	Species
β-Galactosidase	Lactose hydrolysis in food matrix	Improved growth in milk	Wide-ranging
	Lactose hydrolysis in the GI tract	Improved lactose hydrolysis in GI tract for population suffering of lactose maldigestion	Yogurt starters *Streptococcus thermophilus L. delbrueckii ssp. bulgaricus*
NADH oxidase and NADH peroxidase	Eliminate H_2O_2	Improved stability in presence on oxygen	Lactobacilli and bifidobacteria—strain variable
ATPases	Excretion of protons (H^+) from cells to outer medium	Reduced intracellular drop in pH and increased survival to gastric transit	Many LAB (*Streptococcus, Lactococcus and Lactobacillus spp*)
Arginine deiminase pathway	Production of NH_3 and ATP	Reduced intracellular drop in pH and increased survival to gastric transit	Lactobacilli
Bile salt hydrolase	Deconjugation of bile salts	Lowers blood cholesterol level	*Bifidobacterium* ssp. often show high activity, but many *Lactobacillus* ssp. cultures are also active
α-Galactosidase	Hydrolysis of stachyose and raffinose in GI tract	Reduces gas discomforts linked to consumption of beans	*L. plantarum, B. longum*
Proteases	Hydrolysis of caseins, or soy proteins	Produces ACE inhibitory peptides, which are antihypertensive	*L. helveticus*
Glutamate decarboxylase	Conversion of glutamate to GABA	Lowering of blood pressure	*Lactococcus lactis, L. paracasei*
Glucosidases	Deconjugates isoflavones or quercetin from glycosylated forms	Higher levels of the more bioactive forms of antioxidants (cancer, bone metabolism, etc.)	*L. helveticus, L. acidophilus, B. longum, L. plantarum*

GI, gastro-intestinal; ACE, acetyl choline esterase; *L., Lactobacillus; B., Bifidobacterium;* LAB, lactic acid bacteria; GABA, gamma-amino butyric acid.

value of other foods as well. For example, isoflavones are encountered in soy products. The native forms of the isoflavone in soy are mainly daidzein, genistin, and glycitein that are the glycosylated forms. These β-glucosides, are not readily bioavailable in humans as they are unable to be absorbed through the intestinal tract. Hydrolysis of β-glucosides by bacterial β-glucosidases, produces the active and more readily metabolized aglycone forms (Setchell et al. 2002). Many lactobacilli and bifidobacteria possess glucosidases. Thus, the data show that soy fermentation with selected strains contributes to increasing the levels of bioactive aglycons (Champagne et al. 2010).

In summary, many enzymatic activities of lactic cultures contribute to the synthesis, or simply to the release, of probioactives in foods (Table 35.4).

CONCLUSION

Many biochemical processes are critical in the functionality of probiotic bacteria. From a technological perspective, it can be foreseen that cells will be adapted to enhance a specific en-

zymatic activity that will promote their growth or their stability during storage. Minor acid, osmotic, and thermal stresses have been proposed for this purpose (De Angelis and Gobbetti 2004).

As knowledge of the enzymatic systems involved in health functionality of probiotics increases, the requirement for viable cells might gradually be reduced. Thus, the critical element for the health effect may be limited to the enzymatic components, for example, the quantity of the probioactive. The use of pure enzymes might eventually be considered in substitution to probiotics, but only if the enzymes are stable in the matrix and if they survive passage to the GI conditions. Even if it is enzyme-linked, functionality might still require that the enzymes be delivered through a cell, viable or not, in order to protect them against inactivation in the adverse conditions, they will be exposed to in the food or the GI tract. Therefore, more research is needed not only on the biochemical processes involved in the functionality of probiotic bacteria, but also on factors that will enable the "delivery" of the biochemical activity at the proper site.

Biological Activities and Production of Marine-Derived Peptides

Wonnop Vissesangua and Soottawat Benjakul

Abstract: Marine bioactive peptides are known to possess potential health benefits for humans. Beyond their basic nutritional roles, biopeptides are involved into many physiological processes in the living organisms. Many studies have reported that marine-derived bioactive peptides possess angiotensin I converting enzyme (ACE) inhibitory, antioxidant, antimicrobial, calcium binding, anticoagulant, immunomodulatory, and gastrin/CCK-like activity, which can be applied as functional foods and pharmaceuticals. Some of these biological characteristics are attributed to native peptides but also to those generated in vitro by enzymatic hydrolysis and released during processing. The recovery and production of these compounds from various food sources have been investigated for potential commercial applications in the food, health, and allied industries.

INTRODUCTION

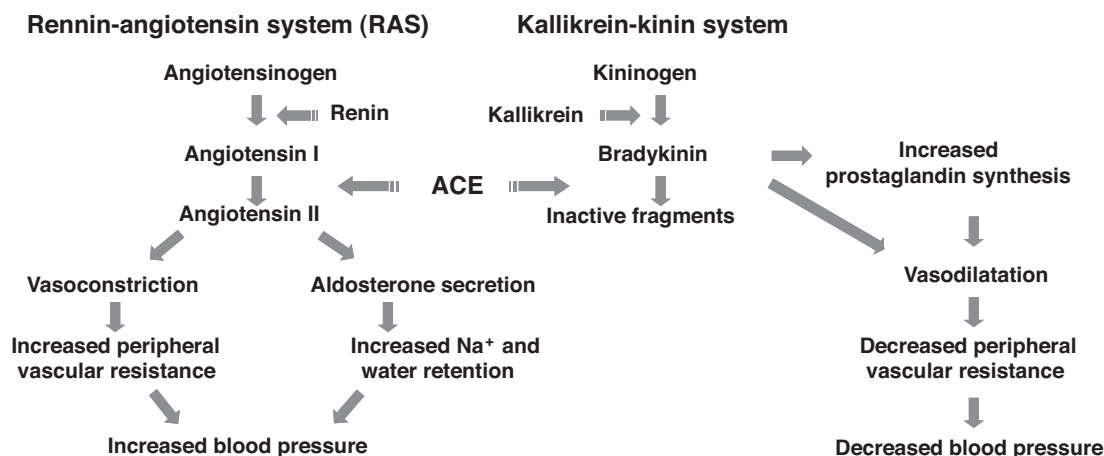
Marine animals are emerging as a leading group for identifying and extracting bioactive peptides (Aneiros and Garateix 2004, Barrow and Shahidi 2008, Kim et al. 2008). These peptides have been described as a source of pharmaceutical products with beneficial effects on humans. Beyond their basic nutritional roles, peptides are involved in many processes in the living organisms on the basis of their physiological functions as hormones, neuropeptides, alkaloids, antibiotics, toxins, and regulation peptides. Depending on the sequence of amino acids, these peptides can exhibit diverse activities with physiological significance. Many studies have reported that marine-derived bioactive peptides possess angiotensin I converting enzyme (ACE) inhibitory, antioxidant, antimicrobial, calcium binding, anticoagulant, immunomodulatory, and gastrin/cholecystokinin (CCK)-like activity that can be applied as functional foods and pharmaceuticals. Some of these biological characteristics are attributed to native peptides but also to those generated in vitro by enzymatic hydrolysis and released during processing. A number of marine-derived bioactive peptides have been discovered. Nevertheless, more studies are being performed to explore the sources especially from underutilized marine processing by-products, their bioavailabilities and possible physiological function, and their mechanisms of action. In addition, technological approaches in terms of production and recovery have also been investigated for potential commercial applications in food industry, biotechnologies, cosmetics, or human health.


Figure 36.1. Role of angiotensin converting enzyme (ACE) in blood pressure regulation.

BIOLOGICAL ACTIVITIES OF MARINE-DERIVED PEPTIDES

ACE INHIBITORY PEPTIDES

ACE inhibition has become an important target in the development of drugs to control high blood pressure, which is a significant health problem worldwide. ACE (EC 3.4.15.1) is a zinc-metallopeptidase that needs zinc and chloride ions for its activity (Erdos and Skidgel 1987). It is widely distributed in mammalian tissues, predominantly as a membrane-bound ectoenzyme in vascular endothelial cells and also in several cell types including absorptive epithelial, neuroepithelial, and male germinal cells (Steve et al. 1988, Sibony et al. 1993). In the renin-angiotensin system (RAS), ACE plays a crucial role in the regulation of blood pressure as well as cardiovascular function (Li et al. 2004). Within the enzyme cascade of the RAS (Fig. 36.1), ACE converts the inactive angiotensin I by cleaving dipeptide from the *C*-terminus into the potent vasoconstricting angiotensin II. This potent vasoconstrictor is also involved in the release of a sodium-retaining steroid, aldosterone, from the adrenal cortex, which has a tendency to increase blood pressure. ACE is a multifunctional enzyme that also catalyses the degradation of bradykinin, a blood pressure lowering nonapeptide in the kallikrein-kinin system (Erdos and Skidgel 1987, Johnston and Franz 1992). Moreover, ACE has been shown to degrade neuropeptides including enkephalins, neurotensin, and substance P, which may interact with the cardiovascular system (Wyvratt and Patchett 1985).

A large number of highly potent and specific ACE inhibitors have been developed as orally active drugs that are used in therapy to reduce morbidity and mortality of patients with hypertension. However, these synthetic drugs, such as captopril, enalapril, alacepril, and lisinopril, which are used extensively, are believed to have certain side effects, such as cough, taste disturbances, and skin rashes angioedema and many other dysfunctions of hu-

man organs (Atkinson and Robertson 1979). Therefore, a search for ACE inhibitors from foods and natural sources has become a major area of research.

Marine-derived ACE inhibitory peptides have been discovered in enzymatic hydrolysates of different marine animals (Table 36.1). These peptides are generally short chain, often carrying polar amino acid residues like proline, lysine, or arginine at *C*-terminal residue (Meisel 1997). Cheung and Chushman (1971) suggested that tryptophan, tyrosine, proline, or phenylalanine at the *C*-terminal and branched-chain aliphatic amino acids at the *N*-terminal are suitable for peptides to act as competitive inhibitors by binding with ACE. Furthermore, structure–activity relationships among variety of peptide inhibitors of ACE indicate that binding to ACE is strongly influenced by the *C*-terminal tripeptide sequence of the substrate, and it is suggested that peptides, which contain hydrophobic amino acids at these positions, are potent inhibitors (Qian et al. 2007).

It has been demonstrated that some marine-derived ACE-inhibitory peptides exhibit higher or comparable in vivo anti-hypertensive activity to captopril (Fujita and Yoshikawa 1999, Lee et al. 2010). By intravenous administration, Fujita and Yoshikawa (1999) reported a reduction in blood pressure by 30 mm Hg in spontaneously hypertensive rats (SHR) by giving Leu–Lys–Pro–Asp–Met, a peptide derived from thermolysis-digest of dried bonito at a dose of $100\,\mu$g/kg. A greater reduction by 50 mm Hg was observed when Leu–Lys–Pro, the hydrolyzed product of Leu–Lys–Pro–Asp–Met by ACE, was given at a dose of $30\,\mu$g/kg. Furthermore, a study conducted over an 8-week period in humans involving 30 subjects with hypertension produced an interesting result that blood pressure was reduced by 60–66% in individuals fed a thermolysis-digest of dried bonito. In another study (Kawasaki et al. 2002), sardine protein hydrolysate incorporated at a dosage of 0.5 g into a vegetable drink was shown in a randomized double-blind placebo-controlled study on 63 subjects over 13 weeks to lower systolic blood

		Val–Lys–Lys	1045 μM	
Blue mussel	Natural fermentation	Glu–Val–Met–Ala–Gly–Asn–Leu–Tyr–Pro–Gly	19.34 μg/mL	Je et al. (2005d)

[a]IC$_{50}$ value is defined as the concentration of inhibitor required to inhibit 50% of the ACE activity.

pressure by 11 mm Hg, while the control group showed no decrease. Lee et al. (2010) reported that a single oral administration (10 mg/kg of body weight) of peptide from tuna frame hydrolysate displayed a strong suppressive effect on systolic blood pressure of SHR and this antihypertensive activity was similar to captopril. Moreover, no adverse side effects were observed in the rats after administration of antihypertensive peptide. Although, the exact mechanisms underlying this phenomenon have not yet been identified, it was suggested that bioactive peptides have higher tissue affinity and are subjected to a slower elimination than captopril.

Currently, protein hydrolysates from the bonito and sardine are widely available as supplements in Japan (Guérard et al. 2010). Bonito hydrolysate is also being sold in North America as a supplement to lower blood pressure. Similar products have been derived from other proteins, including soy and whey.

However, active dosages in these nonmarine products are 1020 g/day, whereas bonito protein hydrolysis, for example, has a recommended daily dosage of only 1.5 g/day. A low daily dose is important for both ingredient cost and ease of formulation. Marine-derived bioactive peptides have potential for use as functional ingredients in nutraceuticals and pharmaceuticals due to their effectiveness in both prevention and treatment of hypertension. However, further studies are needed with clinical trials for these antihypertensive peptides.

ANTIOXIDANT ACTIVITY

Lipid oxidation is one of the major deteriorations in many types of natural and processed foods, leading to changes in food quality and nutritional value and also production of potentially toxic reaction products. Furthermore, lipid oxidations are major

causes of many serious human diseases, such as cardiovascular disease, cancer, and neurological disorders as well as the aging process (Jittrepotch et al. 2006). To prevent foods from undergoing oxidative deterioration and to provide protection against serious diseases, it is important to inhibit the oxidation of lipids and formation of free radicals occurring in the living body and foodstuffs. In this regard, several antioxidants have been used to maintain food quality. Also, there is keen interest in antioxidants from natural sources for use as food supplements or processing aids. The commonly used antioxidants are chemically synthesized antioxidants such as butylated hydroxyanisole, butylated hydroxytoluene, tert-butylhydroquinone, etc. However, these antioxidants are suspected to pose toxicity problems in the long term and their use in foodstuffs is restricted or prohibited in some countries (Sakanaka et al. 2004, Je et al. 2005a, Pihlanto et al. 2008).

Recently, a number of studies have demonstrated that peptides derived from different marine animal protein hydrolysates act as potent antioxidants (Table 36.2). Some of these antioxidant peptides have exhibited varying capacities to scavenge free radicals. Several studies have indicated that peptides derived from marine fish proteins have greater antioxidant properties than α-tocopherol in different oxidative systems (Jun et al. 2004, Rajapakse et al. 2005b). However, the exact mechanism of action of bioactive peptides as antioxidants is not clearly known. Some peptides are capable of chelating metal ions, which acts as the pro-oxidant (Klompong et al. 2007). The antioxidant activity of protein hydrolysates has been attributed to the presence of certain amino acids in the peptide sequence. High amounts of histidine and some hydrophobic amino acids are related to the antioxidant potency. Dávalos et al. (2005) indicated that tryptophan, tyrosine and methionine showed the highest antioxidant

activity among the amino acids, followed by cysteine, histidine, and phenylalanine, while histidine and hydrophobic amino acids were suggested by Peña-Ramos et al. (2004) as the key factors in delaying lipid oxidation. Mendis et al. (2005b) reported that the presence of nonaromatic amino acids such as proline, alanine, valine, and leucine in jumbo squid skin hydrolysate contributed to the higher antioxidative activities, and phenylalanine and leucine residues at *N*- and *C*-terminals of peptide could contribute to the high activity. Wang et al. (2008c) stated that peptides exhibiting good antioxidative activity usually contain certain amino acids such as histidine, proline, tyrosine and lysine. Bougatef et al. (2010) indicated that peptides containing histidine, tryptophan and tyrosine residues possessed antioxidative activity. Guo et al. (2009) concluded that peptides containing tyrosine residues at the *C*-terminus, lysine or phenylalanine residues at the *N*-terminus, and tyrosine residues in their sequences had strong free radical scavenging activity. Moreover, Suetsuna et al. (2000) indicated that some other amino acids such as proline, alanine, and leucine contribute to free radical scavenging activity. Leucine and proline could favor antioxidant activity when they occur at the *C*-terminus end of the sequence (Suetsuna et al. 2000). In general, peptides containing tyrosine tend to exhibit strong free radical scavenging activity due to the phenolic hydroxyl groups, which contribute substantially to scavenging activity toward free radicals via the mechanism of donating a hydrogen atom from their hydroxyl group (Suetsuna et al. 2000, Guo et al. 2009). Other aromatic amino acids, tryptophan and phenylalanine, are generally considered as effective radical scavengers, because they can donate protons easily to electron deficient radicals while at the same time maintaining their stability via resonance structures (Rajapakse et al. 2005b, Zhang et al. 2009). In case of histidine-containing peptides, it is thought to be connected to hydrogen-donating ability, lipid peroxy radical trapping, and/or the metal ion chelating ability of the imidazole group (Mendis et al. 2005a, b). Hydrophobic peptides can help in scavenging of free radicals by keeping close contact with oxidizing substances leading to the rapid scavenging of radicals (Mendis et al. 2005a, b). Some aromatic amino acids and histidine are reported to play a vital role in the observed activity. Gelatin peptides contain mainly hydrophobic amino acids and abundance of these amino acids favors a higher emulsifying ability. Hence, marine-gelatin-derived peptides are expected to exert higher antioxidant effects among other antioxidant peptide sequences (Mendis et al. 2005a). Therefore, marine-derived bioactive peptides with antioxidative properties may have great potential for use as nutraceuticals and pharmaceuticals and a substitute for synthetic antioxidants.

ANTIMICROBIAL ACTIVITY

Antimicrobial peptides (AMPs) have captured the attention of researchers in recent years because of their efficiency in inhibiting pathogens, bacteria, fungi, and virus. Adding preservative is a common way of preventing or slowing microbial growth, the major reason of food spoilage and poisoning. However, there is a shortage of efficient and safe preservatives as a result of appearance of resistant forms of food pathogens in response to massive use of preservatives. Marine-derived AMPs are found in a wide range of marine animals. These peptides are naturally synthesized as a part of innate host defense mechanisms (Brown and Hancock 2006) and may also be generated by enzymatic hydrolysis of native proteins (Bulet et al. 2004, Liu et al. 2008, Reddy et al. 2004). Among the marine animals, they are well described in fish (Kitts and Weiler 2003, Hwang et al. 2010) and the hemolymph of many marine invertebrates, including spider crab (Stensvag et al. 2008), American lobster (Battison et al. 2008), green sea urchin (Li et al. 2008), oysters (Liu et al. 2008), mussels, scallops, venerid clams and abalone (Cheng-Hua et al. 2009), and shrimp (Destoumieux et al. 1997, Bartlett et al. 2002). For example, the mudfish (*Misgurnus anguillicaudatus*) produces a strongly basic peptide termed misgurin (Park et al. 1997). This 2502 Da peptide contains five arginine and four lysine residues and has antimicrobial activity against a broad spectrum of microorganisms. The tissues of Atlantic salmon (*Salmo salar*) contain an antimicrobial peptide with a molecular mass of 20,734 Da. This purified peptide has been identified as a histone protein and is termed histone H1 (Richards et al. 2001). Three antibacterial basic polypeptides, HLP-1, HLP-2, and HLP-3 have been isolated from acetic extracts of channel catfish (*Ictalurus punctatus*) skin (Robinette et al. 1998). The molecular mass of these peptides were reported to be 15.5 kDa, 30 kDa, and 15.0 kDa, respectively. HLP-1 is the dominant peptide and closely related to histone H2B, with inhibitory effects against both fish bacterial pathogens and *Escherichia coli* D31. Catfish (*Parasilurus asotus*) also contains a strong antimicrobial peptide with the molecular mass of 2000 Da, named parasin I consisting of 19 amino acids that include three arginine and five lysine residues (Park et al. 1998). Because of high homology to *N*-terminal sequence of histone H2A, parasin I may be derived from histone H2A by a specific protease cleavage. These AMPs have strong activity against gram-negative and gram-positive bacteria as well as fungi. Potent antibacterial peptides originating from pardaxin have been isolated from Moses sole fish (*Pardachirus marmoratus*) (Shai 1994). Pardaxin is composed of a helix-hinge-helix structure that is a common motif found in many antibacterial and cytotoxic peptides. The peptide, termed pleurocidin, is found specifically in the general epithelial mucous cells of flounder and has an amphipathic α-helical conformation enabling the binding to anionic phospholipid rich membranes. In addition, two hydrophobic proteins with molecular masses of 31 kDa and 27 kDa, respectively, have also been isolated from skin mucous of carp (*Cyprinus carpio*)(Lemaitre et al. 1996). In addition, marine-derived AMPs, such as urechistachykinins, piscidins, and arenicin-1 exhibited significant antimicrobial activities against human microbial pathogens without remarkable hemolytic effects against human erythrocytes (Hwang et al. 2010).

Of marine invertebrates, antibacterial activity has been reported in the hemolymph of the blue crab, *Callinectus sapidus,* and it was highly inhibitory to gram-negative bacteria (Edward et al. 1996). Although there are several reports on antibacterial activity in seminal plasma, few antibacterial peptides have been reported in mud crab, *Scylla serrata* (Jayasankar and Subramonium 1999). The antimicrobial peptide derived from

American lobster (*Homarus americanus*) exhibited bacteriostatic activity against some gram-negative bacteria and both protozoastatic and protozoacidal activity against two scuticociliate parasites *Mesanophrys chesapeakensis* and *Anophryoides haemophila* (Battison et al. 2008). Furthermore, antimicrobial activity and growth inhibition of bacteria such as *E. coli*, *Pseudomonas aeruginosa*, *Bacillus subtilis*, and fungi such as *Botrytis cinerea*, and *Penicillium expansum* have been reported by antimicrobial peptide, CgPep33, derived from oyster (*Crassostrea gigas*) (Liu et al. 2008). In addition, Lee and Susumu (1998) isolated two peptides, Leu–Leu–Glu–Tyr–Ser–Ile and Leu–Leu–Glu–Tyr–Ser–Leu, from thermolysin hydrolysate of oyster, *C. gigas* that inhibited HIV-1 protease. Moreover, an active peptide, Arg–Arg–Trp–Trp–Cys–Arg–X (where X is an amino acid or an amino acid analog) isolated from the enzymatic hydrolysate of oyster, *C. gigas,* showed high inhibitory activity on herpes virus (Zeng et al. 2008). In general, these AMPs are characterized by relatively short cationic peptides with common features, including (1) α-helices, (2) β-sheet and small proteins, (3) peptides with thio-ether rings, (4) peptides with an over-representation of one or two amino acids, (5) lipopeptides, and (6) macrocyclic cystine knot peptides (Epand and Vogel 1999). Their modes of action are based on interaction with the microbial cellular lipid bilayer and eventual disintegration of the cell membrane (Hwang et al. 2010). In addition to antimicrobial action, AMPs have demonstrated diverse biological effects, all of which participate in the control of infectious and inflammatory diseases (Kamysz et al. 2003, Guaní-Guerraa et al. 2010). Therefore, there are several potential applications of AMPs to develop new strategies or substitute the existing ones for more sustainable and promising future of these peptides.

Calcium Binding Peptides

Calcium is an important mineral for the human body. Generally, the principal sources of calcium are milk and other diary products (Anderson and Garner 1996). Casein phosphopeptides (CPP) obtained after intestinal digestion of casein enhance bone calcification (Tsuchita et al. 1993). CPP have the capacity of chelating Ca and preventing the precipitation of Ca phosphate salts, resulting in the increased availability of soluble Ca for absorption (Berrocal et al. 1989, Yuan and Kitts 1994). However, some groups of people do not drink milk due to lactose indigestion and intolerance. Therefore, peptides from other sources, especially from aquatic source can be an alternative for use in food to increase Ca solubility and bioavailability. Bone oligopeptides with high affinity to calcium was prepared from hoki bone with the aid of tuna intestine crude enzyme, which was able to degrade hoki bone matrices comprising collagen, noncollagenous proteins, carbohydrates, and minerals (Jung et al. 2005). Fish bone phosphopeptides (FBP) containing 23.6% phosphorus and a molecular weight (MW) of 3.5 kDa could solubilize calcium (Jung et al. 2005). Fish bone peptide II (FBP II) with a high content of phosphopeptide from hoki bone could inhibit the formation of insoluble Ca salts. The levels of femoral total Ca, bone mineral density, and strength were increased in ovariectomized rats fed with FBP II diet (Jung et al. 2006b). Alaska pollack backbone peptide, Val–Leu–Ser–Gly–Gly–Thr–Thr–Met–Ala–Met–Ala–Met–Tyr –Thr–Leu–Val with the MW of 1442 Da, prepared using pepsin hydrolysis showed affinity for calcium ions on the surface of hydroxyapatite crystals. The peptide could solubilize calcium at levels similar to that by casein phosphopeptide (Jung et al. 2006a). Furthermore, calcium binding peptide derived from pepsinolytic hydrolysate of hoki frame was identified as Val–Leu–Ser–Gly–Gly–Thr–Thr–Met–Tyr–Ala–Ser–Leu–Tyr– Ala–Glu with MW of 1561 Da (Jung and Kim 2007). Therefore, fish bone oligophosphopeptide could be used as the nutraceutical to increase the absorption of calcium.

Anticoagulant Activity

An anticoagulant therapy is a type of medication that may be used to prevent blood from coagulating or clotting. Blood clotting could be life-threatening for patients with atherosclerosis and related cardiovascular diseases, the leading cause of heart attack, stroke, and death (Libby 2002, Levi et al. 2003, Schultz et al. 2003). The mainstays of clinical anticoagulant treatments are heparin, which is a cofactor of plasma-derived and naturally occurring inhibitors of thrombin, and coumarins that antagonize the biosynthesis of vitamin K-dependent coagulation factors. Although effective and widely used, heparins and coumarins have practical limitations because their pharmacokinetics and anticoagulation effects are unpredictable, with the risk of many undesirable side effects, such as hemorrhaging and thrombocytopenia resulting in the need for close monitoring of their use. More seriously, heparins are involved in many aspects of cellular physiology (Kakkar 2003), making their long-term uses as anticoagulants plagued with potential side effects. The anticoagulant marine-derived bioactive peptides have rarely been reported, but have been isolated from marine organisms such as marine echiuroid worm (Jo et al. 2008), starfish Koyama et al. 1998), and blue mussel (Jung and Kim 2009). Moreover, marine anticoagulant proteins have been purified from blood of ark shell (Jung et al. 2001) and yellowfin sole Rajapakse et al. 2005a). The anticoagulant activity of the above peptides has been determined by prolongation of activated partial thromboplastin time (APTT), prothrombin time PT) and thrombin time assays and the activity was compared with heparin, the commercial anticoagulant. The anticoagulant peptide Gly–Glu–Leu–Thr–Pro–Glu–Ser–Gly–Pro–Asp–Leu–Phe–Val– His–Phe–Leu–Asp–Gly–Asn–Pro–Ser–Tyr–Ser–Leu–Tyr–Ala– Asp–Ala–Val–Pro–Arg, isolated from marine echiuroid worm, effectively prolonged the normal clotting time on APTT from 32.3 ± 0.9 to 192.2 ± 2.1 seconds in a dose-dependent manner (Jo et al. 2008). This peptide binds specifically with clotting factor FIXa, a major component of the intrinsic tenase complex. An anticoagulant peptide Glu–Ala–Asp–Ile–Asp–Gly–Asp–Gly–Gln–Val–Asn–Tyr–Glu –Glu–Phe–Val–Ala–Met–Met–Thr–Ser–Lys, derived from blue mussel, showed prolongation of 321 ± 2.1 seconds clotting time on APTT (from 35.3 ± 0.5 seconds of control) and 81.3 ± 0.8 seconds clotting time on TT (from 11.6 ± 0.4 seconds of control), respectively (Jung and Kim 2009). In addition, a

protein derived from the blood of arch shell, prolonged the APTT from a 32 seconds control clotting time to 325 seconds. (Jung et al. 2001). These marine-derived anticoagulant peptides have potential for use as functional ingredients in nutraceuticals or pharmaceuticals.

IMMUNOMODULATORY ACTIVITY

There has been increased interest in the study of the relationship between nutrition and immunity due to the hypothesis that consumption of specific foods may reduce susceptibility for the development and/or progression of immunological diseases. Many immunomodulatory peptides are derived from milk proteins. Some of these peptides have been found to be immunoinhibitory, while others are immunostimulatory in action. Furthermore, it has been found that oral administration of the peptides is a highly effective way to induce the desired immunomodulatory effect, even in the absence of any transport agents such as delivery vehicles. In addition, it has also been found that the amount of peptide required to produce the therapeutic effect by oral delivery can be significantly lower than that required to produce a similar effect when the peptide is delivered by parenteral injection. The immunomodulatory effects of marine-derived bioactive peptides have rarely been reported. Gildberg et al. (1996) reported that four acid peptide fractions from cod stomach hydrolysate were shown to possess an ability to stimulate leucocyte superoxide anion production in Atlantic salmon (*S. salar*). Increasing the production of reactive oxygen metabolites or promoting the phagocytosis and pinocytosis in macrophages can enhance the nonspecific immune defense system. It has been suggested that acid-derived cod protein hydrolysate peptide fractions might be useful as an adjuvant in fish vaccine and as an immune stimulant in fish feed. Immunomodulatory effects of marine oligopeptide preparation (MOP) from Chum Salmon (*Oncorhynchus keta*) were also reported by Yang et al. (2009b). Female ICR mice (6–8 weeks old) were administered the MOP for 4 weeks with the dose of 0, 0.22, 0.45, and 1.35 g/kg/body weight. In comparison with the control group, MOP could significantly enhance the capacity of lymphocyte proliferation induced by the mitogen concanavalin A, the number of plaque-forming cells, natural killer (NK) cell activity, the percentage of $CD4^+$ T helper (Th) cells in spleen and the secretion of Th1 (interleukin (IL)-2, IFN-γ) and Th2 (IL-5, IL-6) type cell cytokines. Nevertheless, no significant differences in weight gain, lymphoid organ indices, and phagocytosis capacity were observed. In irradiation-treated mice (Yang et al. 2010), MOP significantly increased the survival rate and prolonged the survival times for 30 days after irradiation, and lessened the radiation-induced suppression of T- or B-lymphocyte proliferation, resulting in the recovery of cell-mediated and humoral immune functions. This effect may be produced by augmentation of the relative numbers of radioresistant $CD4^+$ T cells, enhancement of the level of immunostimulatory cytokine, IL-12, reduction of the level of total cellular NF-κB through the induction of IκB in spleen, and inhibition of the apoptosis of splenocytes. In addition, it is proposed that MOP can be used as

an ideal adjuvant therapy to alleviate radiation-induced injuries in cancer patients.

The oligopeptide-enriched hydrolysates from oyster (*C. gigas*), produced using the protease from *Bacillus* sp. SM98011 possessed antitumor activity and immunostimulating effects of the oyster hydrolysates in BALB/c mice (Wang et al. 2010). The growth of transplantable sarcoma-S180 was obviously inhibited in a dose-dependent manner in BALB/c mice given the oyster hydrolysates. Mice receiving 0.25, 0.5, and 1 mg/g of body weight by oral gavage had 6.8%, 30.6%, and 48% less tumor growth, respectively. Concurrently, the weight coefficients of the thymus and the spleen, the activity of NK cells, the spleen proliferation of lymphocytes and the phagocytic rate of macrophages in S180-bearing mice significantly increased after administration of the oyster hydrolysates. These results demonstrated that oyster hydrolysates produced strong immunostimulating effects in mice, which might result in its antitumor activity. The antitumor and immunostimulating effects of oyster hydrolysates prepared in this study reveal its potential for tumor therapy and as a dietary supplement with immunostimulatory activity.

GASTRIN/CCK-LIKE ACTIVITY

Different authors have reported the presence of gastrin/CCK-like molecules in protein hydrolysates from fish by-products (Cancre et al. 1999, Ravallec-Ple and Van Wormhoudt 2003). These molecules are the only known members of the gastrin family in humans, and could have a positive effect on food intake in humans and fish species in aquaculture. Gastrin is a gastric hormone that stimulates postprandial gastric acid secretion and epithelial cell proliferation. In humans, there are two different gastrins, one with 17 and one with 34 amino acids residues. CCK is a group of peptides that controls the emptying of the gallbladder, as well as pancreatic enzyme secretion. It is also a growth factor, and regulates intestinal motility, satiety signaling, and inhibition of gastric acid secretion (Rehfeld et al. 2001). Both gastrin and CCK inhibit food intake and share a common COOH-terminal pentapeptide amide that also includes the sequences essential for biological activity. The incorporation of protein hydrolysates including gastrin/CCK-like molecules in functional foods could be of interest for controlling appetite, food intake, and obesity. The production of protein hydrolysates including CCK-like molecules could also be useful in the treatment of paralytic ileus, for the removal of small concrements from the common bile duct and also for the improvement of pancreatic insufficiency caused by long-term parenteral nutrition or chronic pancreatitis (Rehfeld 2004). Above and beyond the stimulation of satiety through bioactive peptides, lipid-lowering effects as well as increasing metabolic rate are also beneficial in fighting obesity.

PRODUCTION OF BIOACTIVE PEPTIDES

ENZYME HYDROLYSIS

Marine bioactive peptides have widely been produced by enzymatic hydrolysis of proteins derived from marine animals (Zhao et al. 2007, Je et al. 2008, Sheih et al. 2009, Šližytė

et al. 2009). These newly formed peptides can retain the biological properties of the native protein or can show new properties. Using appropriate proteolytic enzymes through the control of process parameters such as pH, time, and enzyme/substrate ratio, it is possible to produce hydrolysates whose components may present some interesting biological properties. Especially for food and pharmaceutical industries, the enzymatic hydrolysis method is preferred because of lack of residual organic solvents or toxic chemicals in the products. Hydrolysis can be generally carried out in a thermostatically stirred-batch reactor in which the hydrolysis conditions (pH, temperature, enzyme concentration, and stirring speed) are adjusted in order to optimize the activity of the enzyme used. An initial mixing is usually done to adjust the pH and temperature to the desired values. To obtain the hydrolysate with high stability with less pro-oxidants, the raw materials can be washed to remove heme protein and lipids (Kristinsson 2007). In addition, antioxidants can be added before hydrolysis. To enhance the hydrolysis process, the raw materials may be subjected to size reduction by homogenization. The bone, scales, or skin, which may interfere with enzymatic hydrolysis, should be removed. Thereafter, the selected protease is added into the mixture containing the protein substrate, which is previously adjusted to pH to the desired value. After hydrolysis, the reaction is terminated by inactivation of protease by heat treatment or pH adjustment. The combination of pH and temperature to denature the protease used is another approach to avoid the harsh condition, which may affect the resulting hydrolysate or peptides. The reaction mixture containing the peptides as well as the unhydrolyzed debris is centrifuged or filtered. The supernatant or filtrate is concentrated or dried. The hydrolysate can be an excellent source of peptides with functionalities and bioactivities, which are determined by the types of protease, pretreatment of raw materials, the condition of hydrolysis, and so on. In order to enhance the bioactivity of peptides produced, several approaches have been implemented such as the use of multistep hydrolysis with different proteases (Phanturat et al. 2010). Moreover, it is possible to obtain serial enzymatic digestions in a system using a multistep recycling membrane reactor combined with ultrafiltration membrane system to separate marine-derived bioactive peptides (Jeon et al. 1999, Byun and Kim 2001, Kim and Mendis 2006). This membrane bioreactor technology equipped with ultrafiltration membranes is recently emerging for the development of bioactive compounds and considered as a potential method to utilize marine proteins as value added nutraceuticals with beneficial health effects.

Choices of Enzyme

Different proteases exhibit varying specificities and reaction rates in the hydrolysis of polypeptide chains. Many authors, in view of the economic interest in the recovering of protein from poorly studied species of fish, have compared some commercial proteases in order to test the most suitable one for the substrate employed. The most common commercial proteases reported are both from plant source such as papain (Quaglia and Orban 1987a, 1987b, Hoyle and Merritt 1994, Shahidi et al.

1995) or from animal origin such as pepsin (Viera et al. 1995) and chymotrypsin or trypsin (Simpson et al. 1998). Enzymes of microbial origin have been also applied to the hydrolysis of fish. In comparison to animal- or plant-derived enzymes, microbial enzymes offer several advantages including a wide variety of available catalytic activities, greater pH, and temperature stabilities (Diniz and Martin 1997). Generally, Alcalase® 2.4 L have been repeatedly favored for fish hydrolysis due to the high degree of hydrolysis (DH) that can be achieved in a relatively short time under moderate conditions compared to neutral or acidic enzymes (Hoyle and Merritt 1994, Shahidi et al. 1994, Diniz and Martin 1996, Martin and Porter 1995, Benjakul and Morrissey 1997).

Alternatively, endogenous proteases in the muscle or internal organs can serve as an important source of proteases, which can be used for production of peptides. Khantaphant and Benjakul (2008) used the ammonium sulphate fraction of fish pyloric caeca extract for preparation of gelatin hydrolysate from brown-stripe red snapper skin with 2,2-diphenyl-1-picrylhydrazyl (DPPH) and 2,2-azino-bis (3-ethylbenzothiazoline-6-sulfonic acid) (ABTS) radical scavenging activities. In addition, Phanturat et al. (2010) used the pyloric caeca extract from bigeye snapper (*Priacanthus macracanthus*) for preparation of gelatin hydrolysate with antioxidative activity. The antioxidative peptide of gelatin hydrolysate produced had MW of 1.7 kDa. To maximize autolysis or hydrolysis, optimal pH and temperature are implemented, thereby enhancing the cleavage of peptides. Nevertheless, it could be difficult to control the DH or obtaining the desired peptides by autolysis or the use of endogenous protease.

The impact of the enzyme's specificity is a key factor influencing both the characteristics of hydrolysates and the nature and composition of peptides produced. Proteolysis can operate either sequentially, releasing one peptide at a time, or through the formation of intermediates that are further hydrolyzed to smaller peptides as proteolysis progresses, which is often termed "the zipper mechanisms" (Panyam and Kilara 1996). Depending on the specificity of the enzyme, environmental conditions and the extent of hydrolysis, a wide variety of peptides can be preferentially generated.

Hydrolytic curves reported for enzymatic hydrolysis of different protein substrates by protease generally exhibited an initial fast reaction followed by a slowdown. With regards to the effect of the enzyme concentration, it was found that the DH increased with higher enzyme concentrations. Less important increases were found with enzyme treatment at higher concentration. The exact concentration of enzymes required to hydrolyze the substrate at a required DH could be calculated when log10 (enzyme concentration) versus DH were plotted (Benjakul and Morrissey 1997). Diniz and Martin (1996) used response surface analysis to study the effects of pH, temperature, and enzyme/substrate ratio on the DH of Dogfish proteins. The polynomial model they proposed was well adjusted to the experimental data and was sufficiently accurate for predicting the DH for any combination of independent variables within the ranges studied. However, it should be realized that the higher DH could also negatively affect the biological activity of peptide.

The hydrolytic reaction also depends on the availability of susceptible bonds, on which the primary enzymic attack is concentrated, and on the physical structure of the protein molecule (Raghunath 1993). Very little is known about the factors limiting enzyme activity. The hypothesis explaining the downward curvature could be related to one of the following phenomena: a decrease in the concentration of peptide bonds available for hydrolysis, enzyme inhibition, or enzyme deactivation. To obtain more information about enzyme deactivation or inhibition, the activity enzyme could be assayed during the course of hydrolysis, compared at the beginning and during the course of the hydrolysis. A regular decrease in the areas observed during the course of hydrolysis suggests an enzyme deactivation or an enzyme inhibition by the inhibitory peptides, which are continuously solubilized during hydrolysis. Such behavior also suggests possible deactivation of the enzyme over the time due to a low stability, including the possibility that the enzyme hydrolyzes itself. This observation together with the results of the extra enzyme and substrate additions makes it possible to conclude that the shape of the hydrolysis curves can be explained as a result of the lack of peptide bonds available for hydrolysis combined to a partial enzyme deactivation during the course of hydrolysis.

Choices of Substrates

Muscle of different fish species have been used for the production of protein hydrolysate such as capelin (*Mallotus villosus*) (Amarowicz and Shahidi 1997), Atlantic salmon (*S. salar*) (Kristinsson and Rasco 2000), mackerel (*Scomber austriasicus*) (Wu et al. 2003), herring (*Clupea harengus*) (Sathivel et al. 2003), smooth hound (*Mustelus mustelus*) (Bougatef et al. 2009), yellowstripe trevally (*Selaroides leptolepis*) (Klompong et al. 2007), red salmon (*Oncorhynchus nerka*) (Sathivel et al. 2005), round scad (*Decapterus maruadsi*) (Thiansilakul et al. 2007), tilapia (*Oreochromis niloticus*) (Raghavan et al. 2008), silver carp (*Hypophthalmichthys molitrix*) (Dong et al. 2008), and loach (*M. anguillicaudatus*) (You et al. 2009). Recently, tuna dark muscle has been used for production of hydrolysate containing antioxidative peptides (Hsu 2010). For some fish species, their myofibrillar proteins were isolated as protein isolate prior to enzymatic hydrolysis such as channel catfish (*I. punctatus*) (Theodore et al. 2008). The protein isolate might be more preferable for the proteinase used. As a consequence, hydrolysis could take place at the higher degree, compared with that found in the intact muscle. Moreover, oyster (*C. gigas*) protein (Qian et al. 2008b) and giant squid muscle (Rajapakse et al. 2005b) were also used as source of protein hydrolysate with the antioxidative activity.

By-products obtained from fish-processing plants have been used for the preparation of protein hydrolysate with functional properties and bioactivities. In general, a variety of proteases have been used to cleave the protein, resulting in the peptides with varying functional properties and bioactivity. By-products (heads, viscera, frames, skin, trimmings) of black scabbardfish (*Aphanopus carbo*) (Bougatef et al. 2010) and those (head and viscera) from sardinella (*Sardinella aurita*) were used to produce the protein hydrolysate. The frames from yellowfin sole (Jun

et al. 2004), Alaska ollack (Je et al. 2005c), and hoki (*Joohnius belengerii*) (Kim et al. 2007) as well as backbones from tuna (Je et al. 2007) and Atlantic cod (*Gadus morhua*) (Šližytè et al. 2009) have been used for the preparation of protein hydrolysates. Apart from solid by-products, liquid effluent such as cooking juice from tuna (Jao and Ko 2002, Hsu et al. 2009) have been used as the raw material for hydrolysate production.

Protein hydrolysates were also prepared from gelatin extracted from aquatic animals. Gelatin hydrolysates with the antioxidative activity have been produced from gelatin from the skin of Alaska pollack (Kim et al. 2001), hoki (Mendis et al. 2005a), cobia (Yang et al. 2008), and sole (Gimenez et al. 2009). Furthermore, gelatin hydrolysates were also prepared from the skin of jumbo squid (Mendis et al. 2005b), bullfrog (Qian et al. 2008a), and squid (Gimenez et al. 2009). These hydrolysates were mainly prepared with the aid of proteolytic enzymes. Since gelatin can be hydrolyzed at high temperature, thermal hydrolysis was applied to produce the gelatin hydrolysate from cobia and tilapia skins (Yang et al. 2008, 2009a). Recently, a protein hydrolysate from gelatin from the Nile tilapia scale with the antioxidative activity was prepared by Ngo et al. (2010).

Microbial Fermentation

Fermented fishery products are a good source of peptides and amino acids, and rich sources of structurally diverse bioactive compounds. Thus, fishery proteins are of particular interest due to their high protein content and diverse physiological activities in the human organism. A great variety of naturally formed bioactive peptides have been found in fermented fishery products. In fermented marine food sources, enzymatic hydrolysis has already been carried out using microorganisms; thus, bioactive peptides can be purified without further hydrolysis (Je et al. 2005b, Je et al. 2005d).

Proteolysis is an important biochemical process occurring during fermentation. It is likely to be constituted by a very large and complex group of enzymes, which differ in properties such as substrate specificity, active site and catalytic mechanism, pH and temperature optima, and stability profile. In general, enzymes important in fermentation may originate from four general sources: (1) viscera and digestive systems, (2) muscle tissue, (3) plant raw materials added to the fermentation, and (4) microorganisms active in the fermentation.

Proteolytic microorganisms play an important role during fishery fermentation. There are several groups of microorganisms that are well known for excretion of proteolytic enzymes capable of degrading proteins. Many types of microbes excrete proteolytic enzymes, including *Aspergillus spp.*, *Bacillus spp*, halophilic bacteria, halotolerant and lactic acid bacteria (Mackie et al. 1971, Lopetcharat et al. 2001). Careful selection by seeding or controlling the growth environment within the fermentation chamber enables the desired microbes to flourish and produce significant quantities of proteolytic enzymes that help to hydrolyze the fish protein (Wheaton and Lawson 1985).

From our study, ACE inhibitory activity and antioxidative activity of peptides extracted from various Thai traditional

TE, Trolox equivalents.
[a]Mean $\pm$ SD from duplicate determinations.
[a–v]Different superscripts in the same column indicate significant differences ($p < 0.05$). ACE inhibitory activity of soluble fractions from some traditional fermented fishery products was assayed at a final concentration of 3 mg dried extraction/mL.
DPPH, 2,2-diphenyl-1-picrylhydrazyl; ABTS, 2,2-azino-bis (3-ethylbenzothiazoline-6-sulfonic acid); FRAP, ferric reducing antioxidant power.

fermented fishery products were studied (Table 36.3). *Pla-som* had the highest inhibition of ACE, whereas *Bu-du*, *Kung-chom*, and *Kem-buk-nud* exhibited the highest DPPH radical scavenging activity, ABTS radical scavenging activity, and ferric reducing antioxidant power (FRAP) ($p < 0.05$), respectively. On the basis of principal component analysis (PCA), peptides with high ACE inhibitory activities were likely to be found in products with low pH and low salt content. The presence of these peptides was probably related to the use of garlic and raw material used but not affected by the ratio of free and total free α-amino acids (F/T ratio). For antioxidative activity, peptides with high FRAP

were likely to be found in products with high F/T ratio. Products with high DPPH radical scavenging activity generally had high ABTS radical scavenging activity but both activities showed no correlation to pH, salt content, and F/T ratio. Therefore, some Thai traditional fermented fishery products might serve as possible protective agents in human diets to reduce damage from high blood pressure and oxidative stress.

The fish silage processing technology developed in the late 1970s revealed the possibility of recovering pepsins and bioactive peptides from fish silage. Silage generally refers to the process of preserving wet fodder, that is, whole fish or parts of fish
Figure 36.2. Protecting groups commonly used in solid phase peptide synthesis.

and so on, by adding acid or by the anaerobic production of lactic acid by bacteria. Whereas the pepsins are used for gentle bio-processing of certain fishery products, the peptides occurred by autolysis may be valuable immune stimulants (Gildberg 2004). In vitro and in vivo studies have shown that certain peptide fractions in fish protein hydrolysates may stimulate the nonspecific immune defense system. Both fish sauce and fish silage are protein hydrolysates with immune stimulating properties. Generally, fish sauce is regarded as a typical Asian product made from tropical fish species, but ancient literature reveals that fish sauce was a common food product in Southern Europe more than 2000 years ago. Recent studies have shown that it can be made also from cold water species.

CHEMICAL PEPTIDE SYNTHESIS

On the basis of the peptide sequences available in all published sources and existing peptide databases (Liu et al. 2008), for example, the EROP-Moscow oligopeptide database, SwePep database, peptide of interest can be obtained through chemical synthesis with appreciable purity and reasonable price. Peptide synthesis is a chemical process of coupling of the carboxyl group of one amino acid to the amino group of another amino acid. Usually, chemical techniques are used to synthesize peptides of up to 30–40 amino acids length. Peptide synthesis process can be classified on the basis of used techniques and type of the final product. Liquid-phase peptide synthesis can be divided into two types, step-by-step peptide synthesis with subsequent adding of one amino acid at ones from C-terminal to N-terminal and block-synthesis with coupling of polypeptide fragments. Liquid-phase peptide synthesis is used in large-scale peptide production for industry. In contrast, solid phase peptide synthesis (SPPS) is a process during which the polypeptide chain is covalently bound via linker to the porous insoluble bed particles (Merrifield 1963). SPPS involves two stages in which the first stage of the technique consists of peptide chain assembly with protected amino acid derivatives on a polymeric support. The second stage of the technique is the cleavage of the peptide from the resin support with the concurrent cleavage of all side chain protecting groups to give the crude free peptides. Currently, two protecting groups are commonly used in solid phase peptide synthesis—Fmoc or 9-fluorenylmethyl carbamate and t-Boc or di-tert-butyl dicarbonate (Fig. 36.2). Fmoc chemistry is known for generating peptides of higher quality and in greater yield than t-Boc chemistry. Impurities in t-Boc-synthesized peptides are mostly attributed to cleavage problems, dehydration, and t-butylation. The advantage of Fmoc is that it is cleaved under very mild basic conditions (e.g., piperidine), but stable under acidic conditions. After base treatment, the nascent peptide is typically washed and then a mixture including an activated amino acid and coupling reagents is placed in contact with the nascent peptide to couple the next amino acid. After coupling, noncoupled reagents can be washed away and then the protecting group on the N-terminus of the nascent peptide can be removed, allowing additional amino acids or peptide material to be added to the nascent peptide in a similar fashion. After cleavage from the resin, peptides are usually purified by reverse phase high-performance liquid chromatography using columns such as C-18, C-8, and C-4. The primary advantage of SPPS is its high yield. With modern SPPS instrumentation, coupling and deprotection yields greater than 99.99%, giving an overall yield of greater than 99% for a 50 amino acid peptide.

PRODUCTION OF PEPTIDES BY RECOMBINANT DNA TECHNOLOGY

Technologies for heterologous protein expression have been invented and developed exponentially (Terpe 2006). Although there are a variety of expression systems by which a protein or peptide can be recombinantly produced, expression of a peptide in a recombinant host cell has met with limited success. Frequently, peptides are poorly expressed in bacteria because intracellularly the peptide may encounter one or more difficulties including insolubility, instability, and degradation. If a peptide is successfully produced recombinantly and purified, such isolated peptide may have reduced biological activity compared to the same amino acids that are part of the protein from which the peptide sequence is derived. Such reduced activity is typical because the active domain of the peptide is conformational rather than linear; and thus, in solution, the isolated peptide does not occur in proper conformation for full biological activity, or such proper conformation is only one of many alternative structures of the peptide.

To overcome the difficulties encountered in expression of peptides, there have been various attempts to express a peptide in a conformation reflective of the conformation of the peptide when expressed as part of the protein from which it is derived. One of those approaches is to express the peptide as part of a fusion protein (Liu et al. 2007). Typically, a fusion protein consists of a microbial (e.g., bacterial) polypeptide backbone into which is incorporated an amino acid sequence representing one or more heterologous peptide sequences. A step in fusion protein expression comprises inserting into a gene, encoding the microbial polypeptide, a nucleic acid sequence encoding one or more heterologous peptides. Usually, the gene is part of an expression vector, such that when the vector is introduced into a host cell system, the fusion protein is then produced either as remaining host cell-associated, or secreted into the culture medium of the expression system. In the art of recombinant protein expression, there remains a need for new systems, and new compositions for the production and delivery of biologically active and stable peptides for use. For example, necessary control elements for efficient transcription and translation (promoters and enhancer sequences) that are compatible with, and recognized by the particular host system used for expression must be incorporated. In the case that the fusion protein may be lethal or detrimental to the host cells, the host cell strain/line and expression vectors may be chosen such that the action of the promoter is inhibited until specifically induced. A variety of operons such as the trp operon, are under different control mechanisms. The trp operon is induced when tryptophan is absent in the growth media. The P_L promoter can be induced by an increase in temperature of host cells containing a temperature sensitive lambda repressor. In this way, greater than 95% of the promoter-directed transcription may be inhibited in uninduced cells. Thus, expression of the fusion protein may be controlled by culturing transformed or transfected cells under conditions such that the promoter controlling the expression from the fusion sequence encoding the fusion protein is not induced, and when the cells reach a suitable density in the growth medium, the promoter can be induced for expression from the inserted DNA. Accordingly, a recombinant DNA molecule containing a fusion sequence, can be ligated into an expression vector at a specific site in relation to the vector's promoter, control, and regulatory elements so that when the recombinant vector is introduced into the host cell, the fusion sequence can be expressed in the host cell. The recombinant vector is then introduced into the appropriate bacterial host cells, and the host cells are selected, and screened for those cells containing the recombinant vector. Selection and screening may be accomplished by methods known, depending on the vector and expression system used (*E. coli*, *B. subtilis*, yeast, fungi, mammalian, and insect cells). Bacterial expression is the usual starting point for expression of heterologous proteins. Bacterial fermentations are inexpensive and can reach high cell densities resulting in high volumetric yields of the target protein. The use of *B. subtilis* has many advantages, such as its GRAS status and easy and inexpensive culturing methods that can result in very high cell densities. Baculovirus/insect cell systems have found wide application for the expression of highly recalcitrant proteins such as protein tyrosine kinases. As with bacterial expression systems, yeasts (*Saccharomyces cerevisiae* and *Pichia pastoris*) offer relatively inexpensive growth media and high-density fermentation. Furthermore, yeast offers the capability of carrying out limited posttranslational modifications such as disulfide bond formation and glycosylation. Mammalian cell expression has become the system of choice for production of complex, glycosylated biotherapeutic proteins such as antibodies, growth factors, and fertility hormones. Several developed methodologies appropriate for large-scale industrial production of intact recombinant peptides in bacteria have been developed without significant toxicity and a complicated purification method. Using this technology, pilot-scale fermentation can be performed to produce large quantities of biologically active peptides. Together, this new method represents a cost-effective means, compared to chemical peptide synthesis to enable commercial production of peptides in large-scale under good laboratory manufacturing practice (GMP) for application in humans.

MEMBRANE TECHNOLOGY

Membrane processes involve separating components by means of selective permeability through the membrane according to flow under pressure over the surface of membrane. The technology is actually a family of processes that include reverse osmosis, nanofiltration, ultrafiltration, and microfiltration, which can be differentiated by the separation range (Short 1995). Because of the fact that the differences in physicochemical properties of active sequences are often small, the specific separation of one or more peptides from a raw hydrolysate is difficult. Until now, ultrafiltration has provided the best method available for the enrichment of peptides (Korhonen and Pihlanto 2006, Kozlov and Moya 2007), but the selectivity between peptides of close similar MW is poor. Among them, ultrafiltration has been widely used to enrich bioactive peptides from protein hydrolysates by which enzymatic hydrolysis can be performed through either

conventional batch hydrolysis or continuous hydrolysis using ultrafiltration membranes.

Ultrafiltration is a pressure-driven membrane process that generally uses membranes with pore sizes in the range of 0.05 μm−1 nm at pressures from 10 to 100 psi to remove both ionic species and low MW solutes from the stream being processed (Short 1995). Ultrafiltration can offer a great advantage to recover and concentrate a small amount of substances from a large volume of liquid phase. Since a positive pressure is employed as a driving force to push the liquid phase through the membrane pores without involving a phase change, ultrafiltration is especially suitable for the separation of sensitive biological substances with activity, such as enzymes. While water and particles smaller than membrane pores pass through, larger molecules, that is, colloids, emulsion droplets, and particulates, are retained and concentrated. Ultrafiltration processes have three distinctive characteristics from the conventional filtration process: (1) they are cross-flow systems in which the solution flows parallel to the membrane surface, clearing away any particles accumulated on the membrane surface, (2) they are critically dependent on membrane materials and their nominal MW cutoff (MWCO), and (3) they depend on membrane geometry in the actual equipment that highly affects the efficiency of the entire process (Belter et al. 1988). The mechanism of separation is complex and is influenced by numerous factors,

such as, method of membrane manufacture, composition of the membrane, chemical interactions between the feed stream and the membrane, fluid dynamics of the membrane, pressure, temperature, and velocity of the feed stream (Dziezak 1990). The main problem in many ultrafiltration processes is fouling or the buildup of a layer on the membrane surface until the retained mass offers hydrodynamic resistance and interferes with flux (Paulson and Wilson 1987). Although conventional pressure-driven processes have characteristics that make them capable of performing most of the separations required economically, their fouling problems dramatically reduce their efficiency and selectivity when separating similar sized molecules.

In order to improve the yield and selectivity of peptide separation from hydrolysates, integrative processes based on the use of electrodialysis and filtration membrane (EDFM) have been recently developed (Bazinet et al. 2005, Bazinet and Firdaous 2009). EDFM combines size exclusion capabilities of filtration membranes with the proper MWCO range with the charge selectivity of electrodialysis. With no pressure applied to the ED cell, only the charged molecules migrate under the electrical field and the neutral molecules theoretically stay in the primary solution and do not pass the filtration membrane. In addition, the ED cell can be configured into multicompartment to perform simultaneous sequential separation of different cationic or anionic peptides (Fig. 36.3). The application has been tested for the purification
Figure 36.3. Configuration of the electrodialysis (ED) cell and filtration membrane (FM) for simultaneous sequential fractionation of anionic and basic peptides. AEM, anion-exchange membrane; UFM, ultrafiltration membrane; CEM, cation-exchange membrane.

or separation of bioactive peptides (Poulin et al. 2006, 2007, 2008). EDFM represents a reliable and cost-effective separation technique, especially when compared to traditional methods, such as chromatography. Further scale-up developments will be necessary to confirm its feasibility at large scale.

Chromatography

Chromatography offers a variety of methods to separate peptides based on charge, hydrophobicity, size, and molecular recognition. Chromatography is a powerful technique to achieve high degrees of purity. It has been well established in biotechnological industries as a production scale unit operation and as an analytical tool to monitor the quality of raw materials and end products and the purification efficiency of sequential downstream operations. Much effort has been given to develop selective column chromatography methods that can isolate and purify bioactive peptides. However, lesser reported are the advances in preparative chromatography of bioactive peptides. This area will play an increasingly important role in the cost-efficient and environmentally acceptable manufacture of bioactive peptides. Purification of peptides may be performed via different separation techniques used separately or in combination. Some, like crystallization or precipitation, are fairly well established, although they are constantly being improved. Others, like liquid–liquid extraction, chromatography, and electrophoresis, are being developed with a view to being scaled up in the near future.

CONCLUSIONS

Marine-derived bioactive peptides play a vital role in human health and have potential as active ingredients for preparation of various functional foods and pharmaceutical products. The possibilities of designing new functional foods and pharmaceuticals based on marine-derived peptides to support reducing or regulating diet related chronic ailments are promising. These peptides can be naturally formed by hydrolysis by proteolytic enzymes or fermentation. Furthermore, fish processing by-products can be easily utilized for producing bioactive peptides. Until now, most of the biological activities of marine-derived bioactive peptides have been observed in vitro or in mouse model systems. Human clinical studies are limited or nonexistent. Therefore, further research is needed in order to clarify the relevance and potential therapeutic role of bioactive peptides in human subjects. A few commercial food products supplemented with marine-derived bioactive peptides have been launched in limited markets. As part of a normal dietary regimen, they must demonstrate their effects in amounts that are reasonably expected to be consumed. Recently, industrial-scale technologies suitable for the industrial production of bioactive peptides have been developed. The multifunctional properties of marine-derived peptides appear to offer considerable potential for the development of many similar products in the near future.

Natural Food Pigments

Benjamin K. Simpson, Soottawat Benjakul, and Sappasith Klomklao

Abstract: Nature has endowed living organisms with different pigments for a plethora of functions. These include enhancing the visual appeal of the source material, a means for camouflage and concealments, as an index of food quality, and even as sex attractants. The interest in natural pigments as food-processing aids derives from the increasing consumer aversion to the use of chemicals and synthetic compounds in foods. The chapter provides information on the major types of natural food pigments and their major sources, their functions and uses in food, their health benefits, and their fate under various processing and storage conditions. The chapter also provides information on their relative advantages over their counterparts perceived as artificial food colorants.

INTRODUCTION

Nature relies on a variety of compounds to impart colors to living organisms and to carry out various functions. The colors may be red, purple, orange, brown, yellow, green, blue, or their various shades. In the case of raw unprocessed foods, these compounds or natural pigments enhance their visual appeal to consumers who associate the colors of food with quality and freshness. These natural compounds are widespread in animals, plants, and microorganisms (including algae, fungi, and yeasts). In all these organisms, these compounds display various shades of black, blue, brown, green, orange, pink, red, or yellow colors. Examples of fresh foods with dark or black colors are blackberries, grapes, black beans, black olives; those with brown colors include seaweeds (brown algae), mushroom, cocoa, coffee, and tea; some others with blue or purple colors include blueberries,

aubergines, raisins, currants, plums, pomegranates, and prunes; the kinds with green colors include asparagus, avocado, broccoli, Brussels sprouts, cabbage, celery, cucumber, green beans, green onion, kiwi fruit, lettuce, okra, spinach, and zucchini; examples of the types with orange or yellow colors are crustacea (crabs, lobster, scampi, and shrimps), salmonids (Arctic char, salmon, and trout), carrots, apricots, yellow peppers, mangoes, lemon, pumpkin, pineapple, squash; and the ones with shades of red colors include several fruits and vegetables (e.g., beets, cranberries, raspberries, red bell peppers, strawberries, tomatoes, and watermelon), meats (e.g., beef, hog, and poultry), and seaweeds (red algae).

Although it is their visual appeal that first attracts the consumers' attention to foods, these compounds also carry out a plethora of key functions in living organisms. In certain species, the compounds function as attractants or mating signals to gain the attention of their mates; in some cases, the colors provide camouflage against predators; some of the compounds participate in metabolic processes (e.g., chlorophylls or carotenoids in biosynthetic reactions and energy generation); some others serve as antioxidants and protect vulnerable biomolecules from oxidative damage; some carry out a transport function (myoglobin (Mb) and hemoglobin (Hb) for oxygen (O_2) transport and energy generation); while others play a role in vision or protect skins and membranes against the damaging effects of sunlight and radiation. Thus, it is not surprising that interest in these compounds extends beyond their visual appeal and consumer preferences in foods to also encompass other aspects such as the health benefits they provide. Each of these interests in itself can form the subject matter of an entire book; thus, the focus in this chapter will be on the major natural food pigments and their sources, structures and functions, properties and uses, and some of their important health benefits.

THE MAJOR NATURAL PIGMENT TYPES

For the purpose of this discourse, the term major natural food pigments is used to encompass the heme pigments (Mb and Hb), carotenoids, chlorophylls, anthocyanins, flavonoids, betalains, melanin, tannins, quinones, and xanthones. The heme pigments are the major pigments found in meats; they are water-soluble red, purplish or brownish compounds and they perform O_2 transport and energy generations functions in animal tissues; the carotenoids are bright red, orange, and yellow fat-soluble and water-insoluble pigments widespread in plants, animals, and microorganisms; the chlorophyll pigments tend to occur with the carotenoids and are found in the plastids of photosynthetic organisms (i.e., plants, algae, and certain bacteria); the anthocyanins are water-soluble red, blue, and violet pigments found in several plants (fruits and vegetables) and microorganisms; flavonoids (also known as anthoxanthins) are water-soluble pigments ranging from colorless to yellowish and are found in plant and microbial sources; the betalains are red and yellow water-soluble pigments found extensively in plants; melanins are shades of brown to dark colored pigments formed by the enzymatic oxidation of polyphenolic compounds and are responsible for the dark colorations in animals, plants, and microorganisms; tannins

are colorless to yellow or brown colored pigments found in the barks of certain trees like the oak or sumac; the quinones are a group of pale yellow to dark brown or black pigments also found in plants and microorganisms; and xanthones are yellow-colored compounds found mostly in the plant families of *Bonnetiaceae, Clusiaceae*, and *Podostemaceae*.

THE HEME PIGMENTS (MB AND HB)

STRUCTURES AND FUNCTIONS

The two main heme pigments of interest in foods are Mb and Hb. They are responsible for the red color of meats. The principal function of these two pigments in animal tissues is O_2 transport for the purpose of energy generation. Mb comprises a single polypeptide chain called globin with a molecular weight of approximately 16.4 kDa. This single protein chain is bound to an essential nonprotein four-member ring compound known as porphyrin (or tetrapyrrole) through a central iron (Fe) atom. The Fe can exist in two oxidation states, the ferrous (Fe^{2+}), and the ferric (Fe^{3+}) forms. Both of these forms have a coordination number of six, giving heme the capacity to bind or accept up to six ligands (Fig. 37.1). In both heme pigments (Mb and Hb), the central Fe atom uses four (4) of its coordination positions to bind to the four nitrogen (N) atoms in the porphyrin ring, and its fifth coordination site to bind with a N atom of one of the
Figure 37.1. Tetrapyrrolle ring structure of heme pigments.

histidine residues in globin. The sixth coordination site of the central Fe atom is available for binding with several groups (e.g., CO_2, CO, CN, H_2O, H_2O_2, NO, O_2). Which of these groups (or ligands) can bind to the central Fe atom largely depends on the oxidation state of the Fe. For example, :O_2, :NO, and :CO bind to Fe in the Fe^{2+} state, while -CN, -OH -SH and H_2O_2, bind to Fe in the Fe^{3+} form.

The synthesis of the heme pigments has initial stages that are common to those of the chlorophyll pigments, and lead to the formation of the tetrapyrrole or porphyrin ring structure. The common initial steps (for the heme and chlorophyll pigments) involve the formation of a 5-carbon intermediate compound, 5-aminolevulinic acid (dALA), from smaller molecules like glycine and succinate or glutamate (Beale 1990). Next, two of the dALA molecules combine and cyclicize to form the pyrrol ring compound, porphobilinogen (PBG). Four molecules of the PBGs subsequently form hydroxymethylbilane (HMB) via deamination and complexation reactions, and the HMB molecule formed next undergoes dehydration to form the tetrapyrrole ring compound, uroporphyrinogen (UPP) (Jordan 1989). The heme pigments are formed from UPP via a series of enzyme catalyzed reactions including the insertion of Fe into the tetrapyrrole structure (by ferrochelatase), and its eventual binding to the protein, globin. The chlorophylls, on the other hand, are formed from UPP via a series of enzyme-catalyzed reactions including chelation with magnesium (Mg) by magnesium chelatase, and attachment of the phytol side chain (from phytyl pyrophosphate by chlorophyll synthetase).

In terms of concentrations or levels, Mb is the major pigment of meat muscle. Approximately 80% of muscle pigment is Mb with the balance (approximately 20%) as Hb. Mb traps O_2 in muscle cells as a complex known as oxymyoglobin (MbO_2) for the purpose of producing energy for biological activity in a continuous fashion. Hb, on the other hand, occurs mostly in the blood vessels for O_2 transport. Hb is a tetramer of four Mb units and has a molecular weight of approximately 64 kDa. For this chapter, the focus will be more on Mb than Hb.

MB AND MEAT COLOR

Meats are classified into two types, that is, red (or dark) versus white meats based on the muscle type and the Mb content. The Mb content varies in cells; the higher the Mb content, the more intense the red or dark color of the meat. Thus, red (or dark) meats have relatively higher content of Mb than white meats. This is because red or dark meat comprises muscles that require more uptake of O_2 to be able to generate a constant supply of energy to carry out activities over protracted periods. White meat, on the other hand, has muscle types with lesser Mb content and relies on glycogen as the source of energy for rapid spurts of activity for only brief periods of time. In addition to muscle type, other factors like species, age, sex, and physical activity all influence the Mb levels (and the color) of meat. For example, fresh beef tends to be bright red in color, pork is pinkish, veal is brownish pink, lamb and mutton are pale to brick red, poultry (chicken, ducks, and turkeys) are white to dull red, and most fish tend to range from white to gray. With regards to the physical

state of the meat, the muscle protein in its native state imparts a reddish/purplish color while the denatured form is pinkish to brownish. Furthermore, exercised muscles tend to be darker in color than nonexercised muscles. Thus, the color in the muscles of the same animal can vary depending on the state of activity of the animal. In terms of age, the Mb content tends to increase as the animal gets older (Kim et al. 2003), and the color of female foals were reported in a study to be darker than their male counterparts (Sarriés and Beriain 2006), although Carrilho et al. (2009) found male rabbit meat to be more intensely colored than females rabbit meat. The diets of the animal also affect meat color. For example, cattle raised on pasture has a darker meat color than their counterparts raised on concentrates (Priolo et al. 2001), and there appears to be seasonal variations in meat color with the color being darker in the winter season than in the spring and autumn seasons (Kim et al. 2003).

The color of meat also depends to a large extent on the oxidation state of the Fe present in the porphyrin ring, as well as on the nature of the ligand bound to the sixth coordination position of the central Fe atom. When meats are cooked, the color of Mb changes depending on the extent and/or intensity of the cooking. For example, Mb retains its native color when dark meats are cooked "rare." However, medium cooking causes denaturation of the protein group (globin) and oxidation of the central Fe^{2+} to the Fe^{3+} form, and changes the meat to a tan-colored product known as hemichrome. When meats are "well done," the amount of hemichrome formed increases and the meat acquires a darker brown hue. When white meat is cooked, it changes from a translucent pallor to an opaque or whitish color.

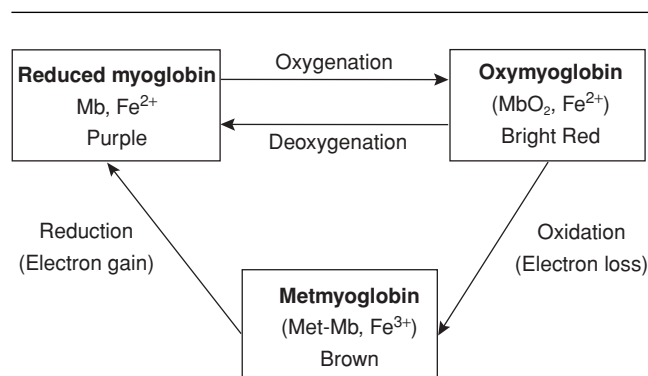
The interconversions between Mb, MbO_2, and MetMb are summarized in Figure 37.2. O_2 adds to purple colored Mb (Fe^{2+}) by oxygenation to form the bright red colored MbO_2 (with the central Fe atom still in the Fe^{2+} form). MbO_2 thus formed may be deoxygenated to regenerate Mb, or oxidized via electron loss to form the brown-colored metmyoglobin (MetMb, Fe^{3+}). MetMb may then undergo reduction by electron gain to re-form Mb (Fig. 37.2).


Figure 37.2. Interconversions between myoglobin (Mb), oxymyoglobin (MbO_2), and metmyoglobin (MetMb).

DISCOLORATION OF MEAT

The color of meats is important because it is used by consumers as an index of quality. In addition to the color changes ascribed previously to the chemical state of the central Fe atom, other factors may also influence the meat color. For example, pale, soft, and exudative (PSE) meats that are characterized by pale colors, soft textures and low water-holding capacities, tend to have considerably more moisture on their surfaces. This is caused by increased glycolysis and a rapid decline in muscle pH that denature meat proteins to adversely impact the texture. Unlike PSE meats, some meats may become dark, firm, and dry due to relatively higher pH levels (>6.0), which make the meat proteins bind water molecules more tenaciously and cause the meat surface to dry out, and reduce light absorption making the meat color to darken. The elevated pH also promotes meat spoilage from microbial proliferation and metabolism. An increase in microbial activity could enhance production of compounds such as amines (via deamination of amino acids) that can react with nitrites (used to "cure" meats) to form nitrosamines in the meats and/or impart a reddish color; or catalase negative bacteria (e.g., lactic acid bacteria) may produce H_2O_2 to give meats a greenish tinge. Exposure of meat to light may cause O_2 to dissociate from MbO_2 in meats to cause fresh meat color to become paler. Antioxidant compounds, for example, vitamin E (α-tocopherol) or vitamin C (ascorbic acid), may be applied to meats to curtail the oxidation of Mb and/or MbO_2 to MetMb, and thereby stabilize meat color. The use of nitrites to "cure" meats is primarily to safeguard against *Clostridium botulinum*, but the process also imparts a pinkish color to meats. Vacuum packaging films also affect the relative proportions of Mb, MbO_2, and MetMb in packaged meats to impact the color from the differences in O_2 permeability or O_2 barrier properties of the packaging films.

HEME PIGMENTS AND HEALTH

Red meats are a good source of Fe (by virtue of Fe being part of the heme). When Fe is deficient, it can cause a reduction in cognitive abilities particularly in children, or result in anemia (i.e., Fe deficiency anemia or IDA). The body requires Fe to synthesize red blood cells and to regulate body temperature, among other things. When a person has IDA, the red blood cell levels decline and the victim's health suffers. People with IDA tend to feel cold on a continuing basis, because regulation of the body's temperature is impaired. Because it is part of Hb and Mb, Fe-deficiency causes people to tire easily since their bodies have insufficient O_2 for both biosynthesis and energy generation.

MEASUREMENT OF MB

A number of procedures have been described in the literature for the measurements of Mb. These include the optical density method by atomic absorption spectroscopy (Weber et al. 1974), differential scanning calorimetry (Chen and Chow 2001), spectrophotometry (Tang et al. 2004), and NIR spectrophotometry (van Beek and Westerhof 1996).

CAROTENOID PIGMENTS

STRUCTURES, SOURCES, AND FUNCTIONS

Carotenoids are ubiquitous in nature and several different members (>400) have been identified in living organisms. One of the best known naturally occurring carotenoid pigment is the yellow-orange colored compound β,β-carotene, which was first crystallized from carrot as far back as in the early 1830s. It is from this source material (carrot) that the name for the entire class of these compounds (carotenoids) is derived. Most carotenoids are water insoluble, but are fat or oil soluble and heat stable. They are found in fruits and vegetables like oranges, tomatoes, and carrots, in the yellow colors of many flowers, in animal species including crustacea (e.g., crab, lobster, scampi, shrimp), fishes (e.g., goldfish and salmonids like Arctic char, salmon, trout) in birds (e.g., canaries, flamingos, and finches), and insects (phasmids, lady bird, and moths); in seaweeds (e.g., *Undaria pinnatifida*, *Laminaria japonica*); in yeasts (e.g., *Rhodotorula rubra*, *Phaffia rhodozyma*); in algae (e.g., *Xanthophyceae*, *Chlorophyceae*); in fungi (e.g., *Blakeslee*, *Xanthophyllomyces*); and in bacteria (e.g., *Corynebacterium autotrophicum*, *Rhodopseudomonas spheroides*). Carotenoids may occur in the free form (e.g., fucoxanthin in seaweeds), or complexed with proteins to form the relatively more stable carotenoproteins as found in several invertebrates (e.g., crustacea). When complexed with proteins, the colors of carotenoids may be altered from orange, red, or yellow to blue, green, or purple. In general, carotenoids are present in low amounts in most organisms, but good sources of this class of pigments include algae and plants (the predominant sources for humans), from fruits (cantaloupe, pumpkin, watermelon, pineapple, citrus fruits, red or yellow peppers, tomatoes, mangoes, papaya, and guava) and vegetables (carrot, rhubarb, sweet potato, kale, parsley, cabbage, collards, and spinach).

Carotenoid compounds are synthesized by plants, bacteria and microalgae from the low molecular weight precursor molecules, pyruvate and acetyl CoA, to initially form a 5-carbon intermediate compound known as isopentenyl pyrophosphate (IPP). IPP has a molecular weight of 246.1 Da and is transformed by a series of enzyme-assisted reactions to form the 40-carbon polyunsaturated hydrocarbon compound known as phytoene ($C_{40}H_{64}$) with a molecular weight of 544.94 Da. Phytoene (Fig. 37.3) subsequently undergoes four desaturation steps to form lycopene ($C_{40}H_{56}$), a hydrocarbon carotenoid with thirteen double bonds (Fig. 37.3). Lycopene thus formed, may isomerize and/or cyclicize to form various other hydrocarbon carotenoids such as α-carotene, β-carotene, and γ-carotene. The hydrocarbon carotenoids may then be hydroxylated by hydrolases to form their oxygenated counterparts such as lutein, astaxanthin, canthaxanthin, cryptoxanthin, and zeaxanthin. Figure 37.3 has the structures of some of the common carotenoid compounds. Various raw materials contain different levels of carotenoids. For example, lutein is abundant in many green plants; carrots and most green fruits and vegetables are rich in α-carotene and β-carotenes; astaxanthin, canthaxanthin, and astacene are the major carotenoids in crustacea and salmonids; astaxanthin is also abundant in mushroom, algae, yeasts, and bird feathers
Figure 37.3. Structures of some common carotenoids (*continued*).

(e.g., flamingos and finches); cryptoxanthin, antheraxanthin, and zeaxanthin are the principal ones in maize; cryptoxanthin and zeaxanthin are also predominant in papaya and cantaloupe; red bell peppers have a high content of capsanthin; tomatoes have high levels of phytoene, lycopene, $\beta\beta$–carotene, neurosporene, and phytofluene; and seaweed and many algae have fucoxanthin, fucoxanthinol, and lactucaxanthin as the major ones.

Unlike plants and microorganisms, animals do not synthesize carotenoid compounds de novo, and must derive these compounds from their diets for various processes, although animals may transform dietary carotenoids to other forms for various functions (Tanaka et al. 1976).

Carotenoids like α-carotene, β-carotene, zeaxanthin, and β-cryptoxanthin are important sources of dietary vitamin A. These molecules are cleaved by dioxygenase in the gastrointestinal tract to release, at least a molecule of retinal, which is subsequently reduced to retinol (or vitamin A); thus, such carotenoid compounds are classed as having provitamin A activity. Vitamin A or retinol is needed in the retina of the eye for vision. Other biological functions of carotenoids include their role in light-harvesting and energy transfer reactions in photosynthesis, and in photo-protection of tissues against the ravaging effects of oxidation by exposure to light. The antioxidant role of carotenoids is well known. As antioxidants, carotenoids protect membranes and tissues from oxidative damage and prevent or minimize serious illnesses such as cancer, heart disease, and nutritional blindness. The antioxidant capacity of carotenoids enables them to ward off degenerative diseases by "quenching" harmful free

Tunaxanthin

Violaxanthin

Fucoxanthin
Figure 37.3. (*Continued*)

radicals and reactive O_2 species such as singlet O_2 from causing damage to cells or tissues. Evidence for this behavior by carotenoids includes studies in men that showed that carotenoids could reduce the risks of heart attacks significantly. The same free radical "quenching" behavior of carotenoids enables them to act as anticarcinogens, whereby they act to lower the incidence of certain cancers (e.g., lycopene in tomatoes and prostate cancer). There is also evidence that carotenoids like lycopene suppress the oxidation of low-density lipoprotein (LDL) and helps to lower blood cholesterol levels. Thus, carotenoids play crucial roles in vision and are effective in slowing down age-related eye disorders, and inhibiting oxidation of LDL that promotes

platelet formation and aggregation and cardiovascular diseases, as well as free radical scavenging to prevent certain cancers and membrane or tissues damage from light (Hadley et al. 2003). Carotenoids also boost the immune system by increasing the activities of lymphocytes, or protecting macrophages and the immune system from damage by ultraviolet (UV) light and X-rays. However, the efficacy of antioxidants like β-carotene in protecting against cancers has been questioned (Albanes et al. 1996), and it has even been suggested that it may actually increase the risk of lung cancer in heavy smokers, and cause a higher incidence of cardiovascular diseases as well as high mortalities (Albanes et al. 1996).

An oxygenated carotenoid pigment touted for its health benefits is fucoxanthin (Fig. 37.3) found in the brown algae (kelp). Fucoxanthin has a molecular formula of $C_{40}H_{60}O_6$, a molecular weight of 658.9 Da, and studies have shown it to induce apoptosis and/or antiproliferative effects on certain cancer cells (Hosokawa et al. 2004, Kotake-Nara et al. 2005). For these and other reasons, there is intensive research afoot on the antioxidant effects of carotenoids, and their role as regulators of the immune system, and there is considerable interest in the production of carotenoids by biotechnological approaches to increase supplies for the demand for these compounds.

PROPERTIES AND USES OF CAROTENOIDS

The market for carotenoids is estimated at approximately a billion US$ per annum (Fraser and Bramley 2004). They are used as colorants (e.g., β-carotene, annatto) to impart colors to many processed foods (e.g., margarine, butter, dairy products, confectionery, and baked goods) beverages (e.g., soft drinks), drugs and cosmetics (Britton 1996). They are also used as nutritional supplements and in animal feeds, for example, as colorants for farmed animals (e.g., poultry eggs, salmon, trout, shrimp, and lobster) (Lorenz and Cysewksi 2000). Carotenoids (e.g., astaxanthin, lycopene, and zeaxanthin) can reduce the adverse side effects such as inflammation and/or pain associated with administration of cyclooxygenase inhibitor drugs (Kearney et al. 2006).

HEALTH BENEFITS OF CAROTENOIDS

The health benefits of carotenoids include protection against cardiovascular diseases (by inhibiting the oxidation of LDL cholesterol), certain cancers (e.g., cervical, gastrointestinal tract, lung, skin, uterine), and age-related macular degeneration and cataracts. Carotenoids inhibit the growth of unhealthy cells while promoting the growth of healthy cells to invigorate the body. Most are antioxidants and are able to absorb light/filter the UV rays of the sun to reduce photo-oxidation, and thereby act to protect cells and tissues against oxidative damage potentiated by free radicals and reactive O_2 species (Krinsky and Johnson 2005, Dembinska-Kiec 2005).

METHODS FOR MEASURING CAROTENOID PIGMENTS

Carotenoid pigments (as astaxanthin) may be measured quantitatively by measuring the absorbance at 485 m in a spectrophotometer (Saito and Regier 1971). Other methods that have been used to study the molecular properties of carotenoids include field desorption mass spectrometry (Takaichi et al. 2003), thin layer chromatography and analysis by gas chromatography (Renstrom and Liaaen-Jensen 1981); high-pressure liquid chromatography (HPLC) (Yuan et al. 1996), or by negative ion liquid chromatography-atmospheric pressure chemical ionization mass spectrometry (negative ion LC-[APC]-MS) (Breithaupt 2004). Other methods described for the measurement of carotenoids include reversed phase HPLC (Burri et al. 2003, Graça Dias et al.

2008), resonance Raman spectroscopy (Bernstein et al. 2004), and by UV/Vis and mass spectra chromatography (Meléndez-Martínez et al. 2007).

CHLOROPHYLLS

STRUCTURE AND FUNCTIONS

Chlorophylls are fat and oil soluble green pigments that occur in the plastids of most plants, algae, and certain bacteria. In these organisms, chlorophylls participate in the biosynthesis of complex biomolecules ($C_6H_{12}O_6$) from simpler ones (CO_2 and H_2O) by the process of photosynthesis. They are the most widely distributed natural plant pigments and are present in all green leafy vegetables, and also occur abundantly in the green algae known as chlorophytes. The chemical structure of chlorophylls comprises a tetrapyrrole (or porphyrin) ring system similar to those of Mb and Hb, except that the central atom of chlorophyll is Mg, and the side chain is a 20 carbon hydrocarbon (phytol) group that is esterified to one of the pyrrole rings (while Mb or Hb has the protein, globin, bound to the fifth coordination position of the central Fe atom). Thus, four pyrrole groups are linked together by a central Mg^{+2} ion to form a porphyrin ring, which together with phytol (a 20-carbon hydrocarbon chain) makes the chlorophyll molecule (Fig. 37.4). When foods containing chlorophyll (e.g., vegetables) are cooked, the chlorophyll may undergo changes in color and/or solubility. The colors that form may be dull green, bright green, or brownish. These different colors are due to changes in the chlorophyll molecule such as loss of the phytol side chain, or the removal of the central Mg^{2+}
Figure 37.4. Structure of chlorophyll.
Chlorophyll

Figure 37.5. Interconversions between chlorophyll pigments.

atom (Fig. 37.5). The phytol side chain may be removed by the action of enzymes (chlorophyllase) and/or acidic conditions, while Mg^{2+} may be removed from exposure to acid and heat treatment. It is the 20 carbon hydrocarbon side chain (phytol) that makes chlorophylls nonpolar and water insoluble. So, its removal from the molecule renders the residual compound water soluble. Alkaline conditions and exposure to light can also induce changes in the chlorophyll molecule (Fig. 37.5).

Because of their light trapping and electron transfer roles in photosynthesis, chlorophyll pigments are considered as the basis of all plant life. Chlorophylls are synthesized via the formation of a porphyrin ring, and the initial steps in the biosynthesis pathway are similar to those of the heme pigments, Mb and Hb, described in Section "Structures and Functions." Chlorophylls exist in nature in different forms (e.g., chlorophylls a, b, c_1, c_2, and d). The differences in these forms arise from subtle changes in either the tetrapyrrole ring itself or in the side chain groups. For example, chlorophylls a and b differ only in the substituent group on C7 of the molecule (i.e., —CH_3 for chlorophyll a, and —CH $=$ O for chlorophyll b), while chlorophylls a and b both have —CH $=$ CH_2 group at the C3 position unlike chlorophyll d that has a —CH $=$ O group.

Chlorophyll is commonly extracted from plant species like spinach, alfalfa, nettles, or grass using organic solvents (e.g., acetone and hexane), preferably in dim light to minimize degradation of the pigment. Exposure to light, air, heat, and extreme pH all adversely affect its stability. Nevertheless, the stability

of chlorophylls against degradation may be enhanced by de-esterification of the chlorophyll and complexation with copper ions.

PROPERTIES, SOURCES, AND USES

Chlorophylls are safe for human consumption and since ancient times humans have ingested chlorophylls in their fruits and vegetables. Commercial sources of chlorophylls include the green algae chlorella, the blue-green algae *Spirulina*, the string lettuce (*Enteromorpha*) and the sea lettuce (*Ulva*); all the sources mentioned previously are used as human food (Ayehunie et al. 1996) in salads and soups. Chlorophylls are used as food colorant and in this regard, can be safely added to several foods either in the pure form or complexed with copper. They are also used in several other applications including cosmetics (soaps, creams, and body lotions), oral hygiene products (mouthwash, toothpaste) as well as confectionary (gums and candies) because of their intense green color. Chlorophyll-colored products are best stored under dry conditions and protection from air, light, and heat to better retain the color. Certain countries have restrictions on the use of copper complexes of chlorophylls in foods and drugs because of the toxicity of copper.

Chlorophyll content in tissues and food materials may be measured spectrophotometrically by the AOCS (2004) official method AK 2–92.

Chlorophylls and Health

Chlorophylls also have several health benefits for humans. They have been shown to be capable of rebuilding the bloodstream (Patek 1936), and to be nontoxic and without harmful side effects even when administered in large doses in various routes (intravenous, intramuscular, or oral). The high Mg content in chlorophyll promotes fertility by increasing the levels and activities of the enzymes that regulate sex hormones. Chlorophylls have antibacterial properties and can be used both inside and outside the body for this purpose (Bowers 1947). They are able to clean out drug deposits and deactivate toxins in the body, cleanse the liver, and reduce problems associated with blood sugar (Colio and Babb 1948). They are also used in deodorizers, to inhibit oral bacterial infections, promote healing of rectal sores, and reduce typhoid fevers (Offenkrantz 1950).

ANTHOCYANINS AND ANTHOCYANIDINS

Properties, Structures, and Functions

Anthocyanins are water-soluble, pH-sensitive, red, purple, and blue pigments found in higher plants. They impart the intricate colors to many flowers, fruits, and vegetables. They also occur in leaves, stems, and roots of plants particularly in the outer cells of these parts of the plant. They are found in almost all the plant families, and in fruits and vegetables the main sources include avocados, blackberries, black currants, blueberries, cherries, chokeberries, cranberries, grapes, prunes, oranges, mangos, aubergines, olives, onions, and sweet potatoes. Anthocyanins (and anthocyanidins) may be considered as members of the flavonoid family of compounds (Section "Flavonoids"), but because of their importance and the extensive attention they have received, a separate section is devoted in this chapter to the discussion of these compounds.

The color of anthocyanins is influenced by acidity; they are red under acidic conditions and turn blue at neutral to alkaline pHs. On the basis of the chemical structures, two types are distinguished; the anthocyanidin aglycones (or anthocyanidins) that are devoid of sugar moieties, and the true anthocyanins are glycosides or sugar esters of the anthocyanidins. They all have a single basic core structure, the flavylium ion (Fig. 37.6) that has seven different side groups (denoted as R in the figure) that may be a hydrogen (H) atom, a hydroxide (—OH) group, or a methoxy (-OCH$_3$) group. The sugars of anthocyanins are esterified to the different side groups, and because there are seven of these positions and several sugars (monosaccharides, disaccharides, and trisaccharides) in higher plants, it is to be expected that several different anthocyanins would occur in nature. Furthermore, the sugars may be acylated with the organic acids that are naturally present in plants (e.g., acetate, citrate, ascorbate, succinate, propionate, malate, and many others) to form acylated anthocyanins. The sugar residues may be monosaccharides, disaccharides, or trisaccharides. When there is only one monosaccharide residue esterified to the aglycone, the anthocyanin may be referred to as a monoside; where esterification is to either two monosaccharide units or one disaccharide unit, the product is known as a bioside; where there are three monosaccharides,

or two disaccharides and one monosaccharide, or a single trisaccharide unit esterified, the compound is referred to as a trioside. Those without sugar molecules are known as aglycones. Some of the common anthocyanidins include: cyanidin, delphinidin, pelargonidin, malvidin, peonidin, and petunidin; and some of the known anthocyanin glycosides are: cyanindin-3-glucoside and pelargonidin-3-glucoside, as well as the glycosides and diglucosides of cyanidin, pelargonidin, delphinidin, and malvidin (Fig. 37.6). Their biological functions include their action as antioxidants whereby they protect plants against the damaging effects of reactive O$_2$ species and UV radiation, and also serve as attractant for birds and insects to flowers for pollination.

Uses of Anthocyanins

Anthocyanins are used as food colorant in drinks, food spreads (jams and jellies), jellos, pastries, and confectioneries because of their intense blue or red colorations. There are, however, some drawbacks in the use of anthocyanins in foods. This is due to their high solubility in water and vulnerability to pH changes. Thus, red cabbage may exhibit a deep reddish color or a purplish or bluish color depending on the pH of the milieu. Other factors such as exposure to high temperature, oxidizing agents (tocopherols, peroxides, and quinones), air, or light are detrimental to the stability of and colors imparted by anthocyanins. Although the sugars in anthocyanins may provide some protection for the molecule against degradation under ambient conditions, the same sugar moieties could elicit browning reactions in food products when the latter are exposed to high temperatures and/or light. The detrimental effects of temperature and air may be slowed down by low temperature storage, with protection from light and air/O$_2$.

Anthocyanins and Health

The toxicity of the anthocyanins is not well documented. But they are believed to be nontoxic even at high concentrations. The compounds are potent antioxidants and have been associated with health benefits such as reduced risk of coronary heart disease, improved visual acuity, and antiviral activity. Studies with pelargonidin and delphinidin (both anthocyanins) have shown both of them to be capable of inhibiting aldoreductase, the enzyme that converts glucose into fructose and sorbitol (Varma and Kinoshita 1976). Inhibition of this enzyme is desirable in preventing complications from diabetes because without the inhibition, the sorbitol and fructose formed could diffuse into the myelin sheath along with fluid (by osmotic action) to cause edema of the myelin sheath in nerves (Levin et al. 1980). Thus, substances like pelargonidin and delphinidin that can inhibit the aldoreductase enzymes would be useful in reducing this type of complications for diabetics. The anthocyanins petunidin, delphinidin, and malvidin have also been shown to enhance the activity of glutamate decarboxylase (GAD), the enzyme that catalyzes the decarboxylation of glutamic acid (HOOC—CH$_2$—CH$_2$—CH(NH$_2$)—COOH) to γ-amino benzoic acid (HOOC—CH$_2$—CH$_2$—CH$_2$NH$_2$) or GABA (for short). GABA is an important neurotransmitter in the brain, and an
Figure 37.6. Structures of common anthocyanins.

increase in the level of GAD is useful not only because of the formation of GABA, but also because it can maintain insulin production in people with type 1 diabetes (Ludvigsson et al. 2008). Petunidin, delphinidin, and malvidin can also inhibit glycerol dehydrogenase, a key enzyme in glycerolipid metabolism (Carpenter et al. 1967), and malate dehydrogenase that participate in both the tricarboxylic acid (TCA) cycle (i.e., the dehydrogenation of malate to oxaloacetate) and in gluconeogenesis (i.e., the synthesis of glucose from noncarbohydrate carbon sources) (Carpenter et al. 1967). Thus, by inhibiting malate dehydrogenase, antioxidants also act indirectly to regulate gluconeogenesis.

MEASUREMENT OF ANTHOCYANINS

Several methods have been reported for the measurement of anthocyanins in samples. These include spectrophotometric pro-

cedures for measuring anthocyanins in wines (Cliff et al. 2007), and the use of HPLC and ultra performance liquid chromatography to measure the pigment levels in food samples (Hosseinian and Li 2008). Other procedures for measuring anthocyanins include pH-differential measurements (Giusti and Wrolstad 2001) and FTIR (Soriano et al. 2007).

FLAVONOIDS

PROPERTIES, STRUCTURES, AND FUNCTIONS

The term flavanoids is used here to refer to a family of compounds produced by plants that are sometimes referred to as anthoxanthins. They are water soluble but have lower coloring power compared to the anthocyanins or anthocyanidins; they range in color from colorless to shades of yellow, and they
Figure 37.7. Structures of common flavonoids.

have a common core structure, the benzopyrone ring (Fig. 37.7), which bears a structural resemblance to the flavylium ion of anthocyanins or anthocyanidins (Fig. 37.6). Flavonoids are subdivided into five sub-classes: the flavanols, the flavanones, the flavonols, the flavones, and the isoflavones. These five groups of compounds exhibit subtle differences in structure, such as degree of saturation or unsaturation, and/or position of substituent groups (Fig. 37.7). Examples of the flavanols are catechin, epi-

catechin, epigallocatechin, epicatechin gallate, epigallocatechin gallate, and theaflavins; examples of the flavanones are butin, hesperidin, hesperetin, naringenin and naringin; the flavonols include azaleatin, quercitin, kaempferol, myricetin, morin, and rhamnetin; members of the flavones family include apigenin, baicalein, chrysin, luteolin, tangeritin, and wogonin; and the isoflavones are typified by daidzein, genistein, and glycitein. The flavonoids have lower coloring power compared with the

anthocyanins or anthocyanidins and range from colorless to shades of yellow. Some common food sources at flavonoids are apples, broccoli, citrus fruits, chocolate, cocoa, grapes, green tea, oolong tea, parsley, red peppers, white tea, yellow onions, celery, soybeans, and thyme.

Like anthocyanins, some flavonoids are esterified with one or more sugar residues. Apart from flavanols (catechins and proanthocyanidins), the other known flavonoids appear to occur in plants and foodstuffs in the esterified forms. A lot of these flavonoid glycosides appear to survive the cooking process, as well as the preliminary digestion steps in the mouth and stomach. However, in the small intestines, it appears only the aglycone forms and the flavonoid glucosides are absorbed and metabolized to form various secondary metabolites; and colon bacteria metabolize flavonoids to facilitate absorption (Manach et al. 2004). Nevertheless, the flavonoids have low bioavailability due to inadequate absorption and their fast removal from the body. Of the flavonoids, the isoflavones are said to be the most bioavailable while the flavanols are the least bioavailable (Manach et al. 2005).

Biological Functions and Uses

Flavonoids also have antioxidant properties and are effective free radical scavengers (Chun et al. 2003). However, most circulating flavonoids are believed to be metabolized intermediates or by-products that have relatively lower antioxidant capacity than the parent flavonoid compounds. Thus, the relative contribution of dietary flavonoids to antioxidant behavior in the body is suggested to be miniscule (Lotito and Frei 2006). By virtue of their polyphenolic nature, flavonoids are also able to act as metal ion chelators to stop ions such as Cu^+/Cu^{2+} and Fe^{2+}/Fe^{3+} from promoting the formation and release of free radicals (Mira et al. 2002). The chelating behavior of flavonoids could also adversely affect intestinal absorption of Fe, thus it is recommended for Fe supplements not to be taken together with beverages high in flavonoids or flavonoids supplements (Zijp et al. 2000).

Flavonoids and Health

Although various suggestions have been made to the effect that high intakes of flavonoids from plant sources do not elicit adverse effects in humans due to their low bioavailability and rapid metabolism and removal from the body, there are some reports indicating that high doses of some flavonoids can cause adverse health effects in some people. For example, some flavonoids like quercitin have been reported to induce nausea, headaches and/or tingling sensations in some people, or renal toxicity or vomiting, sweating, flushing, and dyspnea in certain cancer patients (Ferry et al. 1996, Shoskes et al. 1999). Other reports attribute liver toxicity, abdominal pain, diarrhea insomnia, tremors, dizziness, and confusion sometimes observed from intake of caffeinated green tea extracts to the flavonoids present in tea (Jatoi et al. 2003, Bonkovsky 2006). The flavonoids quercitin and naringenin have also been reported to inhibit cytochrome P450 that is involved in the oxidation of various biomolecules such as lipids, hormones, and xenobiotics (drugs) (Bailey and Dresser 2004). They are

also known to inhibit the enzyme 3-hydroxy-3-methylglutaryl-coenzyme A reductase (HMG-CoA reductase), the regulatory enzyme in the mevalonic acid pathway that leads to the formation of isoprenoid compounds, for example, carotenes, cholesterol, and steroids. The effects of these compounds on drug metabolism have been shown to affect the bioavailability and toxicity of drugs such as amiodarone, atorvastatin, cyclosporine, saquinavir, and sildenafil (Bailey and Dresser 2004, Dahan and Altman 2004). It is partly for this reason that patients are cautioned to avoid taking grapefruit juice when they are on some of these drugs, as grapefruit juice has high levels of quercetin and naringenin, as well as furanocoumarins. Copious consumption of purple grape juice has also been found to inhibit platelet aggregation, and the inhibition has been attributed to the high levels of flavonoids in the juice (Polagruto et al. 2003). On the basis of this, it has been speculated that high intake of some of these flavonoids in conjunction with anticoagulants could make some patients more prone to bleeding (Polagruto et al. 2003).

BETALAINS

Properties, Structures, and Functions

The name betalain is derived from beet vegetable (*Beta vulgaris*) from which it was first extracted. They are red or violet and yellow or orange water-soluble aromatic indole pigments found in plants and fungi (*Basidiomycetes*). Betalains are subdivided into two categories based on their colors as betacyanins (reddish to violet) and betaxanthins (yellowish to orange). Examples of the betacyanins are amaranthine, isoamaranthine, betanin, iso-betanin, phyllocactin, and iso-phyllocactin; and representatives of betaxanthins include dopaxanthin, miraxanthin, indicaxanthin, portulacaxanthin, portulaxanthin, and vulgaxanthin. The betalains are synthesized from tyrosine via several routes. The amino acid tyrosine may be converted to betalains via either dihydroxy phenylalanine (L-DOPA) or dopaquinone; or through spontaneous combination with betalamic acid to an intermediate portulacaxanthin II (Tanaka et al. 2008). The structures of betanin and vulgaxanthin are shown in Figure 37.8. The betalains are most stable within the pH range of 3.5 and 7.0, but they are susceptible to light, heat and air.

Uses of Betalains

Extracts from betalains have been used to color foods since time immemorial, and beetroot extract is currently approved for use as food color in many countries to impart color to juices and wines. In addition, different varieties of beet have been used as a source of sugar (sugar beet), as vegetable (beetroot), and fodder (fodder beet). Beetroot tuber is cooked and eaten like potatoes, and it is pickled and used in salads.

Because of their high solubility in water and susceptibility to light and heat, the use of betalains to color food may be limited, although the dried form of betanin is quite stable. High sugar content has also been shown to impart protection to betalains, thus they are used in soft drink powders, frozen dairy products, and in confectioneries. Gentile et al. (2004) reported that
Figure 37.8. Structures of some common betalains.

betalains have anticancer properties by virtue of their antioxidant and free radical scavenging behavior. They have been shown to inhibit redox state alteration induced by cytokines to protect the endothelium layer that line the internal surfaces of blood vessels. The content of betalains in samples may be measured by the HPLC and LC-MS/MS analyses (Stintzing et al. 2006).

MELANINS

PROPERTIES AND FUNCTIONS

Melanins are dark brown and black pigments found in plants, animals, and microorganisms. They are formed via the enzymatic oxidation of phenolic compounds, for example, tyrosine, through several intermediates like DOPA and quinones, followed by polymerization to form the large molecular weight melanins. The enzymes catalyzing the oxidation of the phenolic compounds are polyphenoloxidases, also known as phenolases or tyrosinases. In animals and humans, melanins occur in the eyes, hair, skins, and peritoneal lining where they protect tissues from the detrimental effects of factors like light or UV radiation from the sun's rays. Damage from UV radiation is potentiated in various ways such as dimerization of thymine in DNA molecules, or by the effects of reactive O_2 species (e.g., singlet O_2 and superoxide radicals (Jagger 1985, Tyrell 1991). Examples of melanins are eumelanin and pheomelanin. Pheomelanin is dark red-brown in color and is thought to be responsible for red hair and freckles in humans, while eumelanin imparts black and brown coloring to skin and hair (Meredith and Riesz 2004).

Microorganisms synthesize melanins as part of their normal metabolism, from where they are passed along the food chain to higher forms of life. In crustacea, the formation of melanins is sometimes referred to as melanosis or "blackspot" formation, and connotes spoilage to consumers—mainly due to their lack of visual appeal. The "blackspot" phenomenon has been extensively studied to develop strategies to control this undesirable effect and products such as glucose oxidase, glucose, catalase mixes, or 4-hexyl resorcinol were found to be effective in controlling blackspot formation in raw shrimp (Ogawa et al. 1984, Ferrer et al. 1989, Yan et al. 1989, Chen et al. 1993, Benjakul et al. 2005). Nevertheless, these same compounds are desirable in other situations, such as protecting against UV radiation from sunlight to prevent damage to the skin and also to minimize glare in the eyes. This feature of melanin has been exploited by PhotoProtective Technologies (United States) in making a variety of eye wear that filter out colors to reduce the risks of macular degeneration and cataracts (Anon 2005). Melanin has also been incorporated in a hair dye, Melancor-NH, for darkening gray hair in humans.

MELANINS AND HEALTH

Melanin deficiency in humans has been linked with certain abnormalities and diseases. Examples include oculocutaneous albinism that is characterized by reduced levels of the pigment in the eyes, hair, and skin, and ocular albinism that affects both eye pigmentation and visual acuity (Peracha et al. 2008). Melanin deficiency has also been linked to deafness (Cable et al. 1994) and Parkinson's disease (Nicolaus 2005).

MEASUREMENT OF MELANINS

Melanin measurements may be carried out by spectrofluorometry (Rosenthal et al. 1973) by measuring the fluorescence induced by excitation at 410 nm and emission at 500 nm, or by spectrophotometric measurement of the rate of melanochrome production from 5,6-dihydroxyindole-2-carboxylic acid and 5,6-dihydroxyindole systems at 540 and 500 nm (Blarzino et al. 1999). Melanin in tissues may also be measured based on spectrophotometry, HPLC, and electron spin resonance spectroscopy (Ito 2006, Hu et al. 1995).

TANNINS

PROPERTIES AND FUNCTIONS

Tannins are a heterogeneous group of water-soluble polyphenolic compounds present in many plants. The term "tannin" originated from the ancient practice of using plant extracts to "tan" leather, thus the name "tanning" is used to describe the process. This process makes use of the capacity of tannins to form cross-links with other biomolecules such as proteins or polysaccharides to "toughen" the textures of otherwise soft materials. Tannins occur mainly in tea, coffee, immature fruits, leaves, and the bark of trees where their function is believed to be one of defense. They have an astringent and bitter taste that is unpleasant to prospective consumers. The best known members of this family of compounds include tannic acid and its breakdown products (ellagic acid, gallic acid, and propyl gallate; Fig. 37.9). Tannic acid is used as a food additive. Foods known to be high in tannins include pomegranates, persimmons, cranberries, strawberries and blueberries, hazelnuts, walnuts, smoked meats and smoked fish, spices (e.g., cloves, tarragon, thyme, and cinnamon), most legumes, and beverages such as wine, cocoa, chocolate, and tea.

Tannins are classified into two main classes, (1) the hydrolyzable and (2) the condensed (nonhydrolyzable) tannins. The hydrolyzable tannins are those that on heating with dilute mineral acids or bases form carbohydrates and phenolic acids (i.e., gallic or egallic acid). The condensed tannins form phlobaphenes (e.g., phloroglucinol) when heated with dilute acids or bases. It is the condensed tannins that are more important in alcoholic beverages such as wines.

Some tannins such as tannic acid and propyl gallate display antimicrobial activity toward foodborne bacteria, aquatic bacteria and off-flavor-producing microorganisms, e.g., tannic acid reduces staphylococcal activity (Akiyama et al. 2001). Thus, they can also be used in food processing to extend the shelf-life of some food products.

TANNINS AND HEALTH

Some of the health benefits of *tannins* include their anti-inflammatory, antiseptic, and astringent properties. They also are effective against diarrhea, irritable bowel syndrome, and skin disorders. However, tannins are metal ion chelators and their binding to metal irons make these mineral elements not readily bioavailable. High intake of tannins could hamper the absorption of minerals such as Fe to result in anemia. They can also cause protein precipitation to interfere with the uptake of nutrients in some ruminants. Foods with high levels of tannins are judged to be of poor nutritional value, because they reduce feed intake, protein digestibility, feed efficiency and growth rates, among other things (Chung et al. 1998). These observations have been linked to tannins decreasing the efficiency in converting absorbed nutrients into new body components (Chung et al. 1998). The intake of foods high in tannins such as herbal teas is also thought to increase the incidence of cancers (e.g., esophageal cancer) and this has led to the suggestion that these compounds may be carcinogenic, but other reports attribute the apparent carcinogenic activity observed to constituents associated with tannins and not the tannins per se (Chung et al. 1998). Some of these observations contradict findings alluding to the anticarcinogenic behavior of tannins (Nepka 2009), or their capacity to reduce the mutagenicity of certain compounds (Chen and Chung 2000). The anticarcinogenic and antimutagenic activities of tannins and related compounds have been attributed to their polyphenolic nature that enables them to behave as antioxidants to check lipid peroxidation (Hong et al. 1995) and the damaging effects of reactive O_2 species (Nakagawa and Yokozawa 2002) in biological tissues. Tannins are also reported to reduce blood clotting, blood pressure, and serum lipid levels (Akiyama et al. 2001). They also induce liver necrosis (Goel and Agrawal 1981), and modulate immunoresponses (Marzo et al. 1990).
Figure 37.9. Structures of some common tannins.

QUINONES

PROPERTIES AND FUNCTIONS

Quinones are a class of heterocyclic organic compounds with structures like cyclic conjugated diones. They have been described as secondary metabolites and are found in several organisms including flowering plants, bacteria, fungi, and to a small extent in animals like insects, sea urchins, corals, and other marine animals (Thompson 1991). The compounds display a plethora of colors from yellow to orange to intense purple to black. Examples of quinones include anthraquinone,
Figure 37.10. Structures of some common quinones.

1,2-benzo- and 1,4-benzo- quinones and naphthaloquinones (Fig. 37.10). Because of their high coloring power, quinones are used as dyes.

Quinones are used for the commercial scale production of hydrogen peroxide (H_2O_2) by the hydrogenation of anthraquinones to hydroquinones, and subsequent transfer of hydrogen (H_2) to O_2 (Schreyer et al. 1972, Drelinkiewicz and Waksmundzka-Góra 2006).

For example:

2-ethyl-9,10-anthraquinone $+ H_2$

$\rightarrow$ 2-ethyl-9,10-anthrahydroquinone

dihydroanthraquinone $+ O_2 \rightarrow$ anthraquinone $+ H_2O_2$
Quinones can also react and form conjugates with amino acids, and the products formed can impact the flavor and color of foods (Bittner 2006).

In nature, some quinones serve as important constituents of biomolecules (e.g., vitamin K_1); some like ubiquinone and plastoquinone in mitochondria participate in electron transfer reactions in aerobic respiration, while plastoquinone in chloroplasts are involved in electron transfer reactions between photosystems 1 and 2 in photosynthesis.

QUINONES AND HEALTH

Quinones and related compounds (e.g., tertiary butyl hydroquinone or TBHQ) have antioxidant properties and the terpenes of hydroquinone are thought to be more potent than the more common antioxidants such as α-tocopherol (Delgado-Vargas and Paredes-López 2003). Some other quinones like the napthoquinones have antibacterial activity and can inhibit various strains of aerobic and anaerobic microorganisms (Didry et al. 1986, Riffel et al. 2002). Some have also been shown to have anticancer or antitumor activities (Smith 1985). For example, dietary intake of certain quinone derivatives was reported to play a role in the prevention of breast cancer (Zhang et al. 2009). Ironically, certain quinones and their derivatives have also been shown to be mutagenic or carcinogenic (Zhang et al. 2009). In this regard, it is reported that extended exposure to some of these compounds increases the incidence of breast cancer. Some metabolic products of quinones are also known to be toxic, and the toxicity appears to arise from either the arylation of sulfhydryls compounds or the production of free radicals and/or reactive O_2 species (Smith 1985).

XANTHONES

PROPERTIES AND FUNCTIONS

Xanthones are a group of heat stable organic compounds with 9H-xanthen-9-one (xanthone) as the core structure (Fig. 37.11). Xanthones occur naturally in tropical plants and about two
Figure 37.11. Structures of some common xanthones.

hundred known compounds in this group have been identified. Well-known examples are α-mangostin, β-mangostin, garcinone B, and garcinone E from the pericarp of mangosteen fruit. Xanthones are said to enhance the body's immune system and also impart other human health benefits such as promoting healthy cardiovascular or respiratory systems, supporting cartilage and joint function (Weecharangsan et al. 2006). Other health benefits attributed to xanthones include their capacity to reduce: allergies, cholesterol levels, inflammation, skin disorders and fatigue, and they also curb susceptibility to infections and help maintain gastrointestinal health (Weecharangsan et al. 2006). They have antioxidant properties and they do this by deactivating free radicals in the body. In this regard, they are said to be even more potent antioxidants than vitamins E and C.

Some applications of xanthones include their use as insecticide and it has been used in this regard against moth eggs and larvae. Xanthone in the form of xanthydrol is also used to verify urea levels in the blood.

OTHER PIGMENTS

Apart from the pigments described above, there are other lesser known natural pigments that are also found in various living organisms. Examples of these include the blue and red chromoproteins (phycocyanin and phycoerythrin) found in the blue-green algae and cyanobacteria. There are also other pigments such as flavins and pterins.

PHYCOCYANIN AND PHYCOERYTHRIN

Phycocyanin is blue pigment found in the blue-green algae and cyanobacteria, while phycoerythrin refers to red pigment found in the red algae commonly referred to as rhodophytes. These pigments are conjugated chromoproteins and they comprise of subunits each with a protein backbone that is covalently linked to open chain tetrapyrrole groups. Their molecular weights range from 44,000 daltons (monomers) to 260,000 daltons (hexamers) (Boussiba and Richmond 1979), and they function as light-absorbing substances together with chlorophyll in photosynthesis.

An example of useful red algae is the *nori* or *Porphyra* that is consumed as food and is used as wraps for sushi and in several other Japanese dishes. These pigments are produced commercially from *Spirulina platensis*. *Spirulina* are blue-green algae and they grow well in warm climates and alkaline waters. The two best known members of the *Spirulina* species are *S. platensis* and *Spirulina maxima*. *S. platensis* is cultivated in California while *S. maxima* are cultivated in Mexico. Phycocyanin and related compounds are thought to have antiviral and anticancer activities as well as immune system stimulatory ability. Phycocyanins also enhance the formation and development of red blood cells to reduce the incidence of anemia (Mathew et al. 1995, Jensen and Ginsberg 2000, Mani et al. 2000, Jensen et al. 2001, Samuels et al. 2002, Shih et al. 2003), and also thought to promote the development of healthy skins. Thus, it is used to treat eczema and psoriasis and some other skin disorders. These pigments occur together with carotenoids and chlorophylls in

the blue-green and red algae. Phycoerythrin, in particular, is believed to facilitate red seaweed subsistence at greater depths in the ocean where hydrostatic pressures are high, unlike the other seaweed species (e.g., brown and green algae) that subsist in shallow waters.

The antioxidant, free radical scavenging, and anti-inflammatory properties of phycocyanin, as well as antiviral activity of the pigment have been demonstrated in studies with laboratory animals (Bhat and Madyastha 2000). Other studies have also revealed protective effects by phycocyanin against neuronal damage and oxidative damage to DNA (Bhat and Madyastha 2001, Piñero Estrada et al. 2001). Phycocyanin is used as a natural food-coloring agent in food products such as yoghurts, milk shakes and ice creams, beverages, desserts, and also in cosmetic products. Phycocyanin is used in medicine to facilitate selective destruction of atherosclerotic plaques or cancer cells by radiation with little or no damage to the surrounding cells or tissue (Morcos and Henry 1989), while phycoerythrin is used as fluorescent dyes for fluorescence activated cell scanning analysis (Hardy 1986).

Other pigments include curcumin found in turmeric. Curcumin is an oil soluble pigment and tends to fade when exposed to light, but it is heat stable. It is used to impart lemon yellow colors in food products such as curry, soups, and confectionery. Riboflavin (or vitamin B2), is a water-soluble and heat stable compound with an intense yellow color. It is used to color and fortify foods like dairy products, cereals, and dessert mixes. Carmine (or carminic acid, $C_{22}H_{20}O_{13}$) is a water-soluble pigment obtained from the female cochineal insect (*Dactylopius coccus*). It is stable to heat and light, and resistant to oxidation; and is used in alcoholic beverages and processed meat products. It is also used as an antirepellant.

SUMMARY/CONCLUDING REMARKS

For some time, interest in synthetic food colors was high because of the perceived disadvantages with natural pigments. These disadvantages include inconsistency in the product quality and yields from batch to batch, susceptibility to factors such as heat, pH, light, and air, as well as the high cost. However, pressure now seems to be increasing for less use of synthetic pigments as food colorants. Consumers are showing higher preference for natural pigments in foods for health safety reasons, and recent studies published in various scientific journals, including the *Lancet*, linked synthetic colors with hyperactivity in children (Harley et al. 1978, McCann et al. 2007). In addition, food regulations in Europe are promoting the use of natural pigments in foods over their synthetic counterparts. And the United States Food and Drug Administration has been petitioned to ban the use of synthetic colors like Yellow 5 and 6, Red 3 and 40, Blue 1 and 2, Green 3, and Orange B in foods, and to require labels on foods that contain these dyes. In addition to their coloring power, some of these natural pigments have also been shown to have more potent antioxidant and free radical scavenging capabilities than the synthetic ones commonly used in foods (Frankel et al. 1996). It is estimated that the world market for food colors is in excess of a billion dollars (United States) annually, and natural

pigments account for about 30% of the market. It is predicted that the market share of natural pigments will continue to grow and surpass that of synthetic colors due to the increasing consumer concerns with the latter.

Thus, what needs to be done is more research to address the disadvantages with the commercial production and use of natural food pigments. Sources of the major food colors (red, blue, and yellow) must be identified; procedures to recover them efficiently and in purer and more stable forms, such as enzyme-assisted treatments (Kim et al. 2005) need to be developed; and treatments and/or conditions to stabilize them such as use in combination with antioxidants need to be exploited.

Thermal Processing Principles

Yetenayet Bekele Tola and Hosahalli S. Ramaswamy

Abstract: Food intended for human consumption must be produced in safe and stable forms to ensure availability, distribution, as well as normal growth and development. Thus, foods are processed in various forms to achieve these desired effects. Thermal processing entails the application of heat energy for food transformation into the desired safe and stable forms. This chapter describes the basic principles of thermal processing and surveys conventional versus novel thermal processing methods currently available for food transformation.

INTRODUCTION

Food processing is used to transform and/or preserve raw ingredients from the farm into various food forms for consumption by human being. Food processing often takes clean, harvested produce or edible portions and uses them to produce attractive and marketable food products. Fresh agricultural products (plant and animal origin), due to their high moisture content, are highly perishable and can be kept only for a short period of time. Especially during peak harvesting seasons, due to large volume of these products, unless and otherwise pertinent measures are taken, the problem leads to spoilage and high economic losses. Furthermore, food products should be available throughout the year in market to fulfill the demand of consumers in all seasons. To do this, we need to minimize postharvest losses and preserve agricultural products in a safe way with no or minimum quality loss. The major emphasis of food processing is shelf life extension by preventing undesirable changes in the wholesomeness, nutritive value, and sensory qualities (Ramaswamy and Marcotte 2006).

Various food processing operations make the food products more attractive, satisfying, safer, and easier to eat. Common food-processing techniques include pasteurization, sterilization, cooking, drying, cooling and freezing, fermentation, addition of preservatives and reduction of water activity, and use of two or more of the above techniques to inhibit or stop chemical, biochemical, and microbiological activities. Most foods available in the market are subjected to some form of thermal processing. Although the canning process started from Nicholas Appert's time in 1809, food processing via the canning process still provides a universal and economic method for preserving and processing foods. Thermal processing of canned foods has been one of the most widely used methods for food preservation during the twentieth century and has contributed significantly to the nutritional well-being of much of the world's population (Teixeira and Tucker 1997).

The two very common industrial conventional thermal food processing technologies in production of canned products are pasteurization and sterilization. Pasteurization is the process of heating liquids and/or solid foods for the purpose of destroying principal pathogens capable of growing under aerobic conditions and reducing the level of spoilage vegetative bacteria, protozoa, and fungi from high acidic foods (pH < 4.5). When pH > 4.5, foods produced by this process should be stored at low temperature to avoid further growth spore forming microorganisms. However, commercial sterilization refers to an intensive heat treatment process that effectively kills or eliminates all pathogens and vegetative microorganisms as well as bulk of spore-forming bacteria from the low acid foods (pH ≥ 4.5). Products produced through this method can be shelf stable for up to two years. In order to reduce the process severity, the thermophilic spore formers are not targeted to be completely eliminated, instead the canned product is advised to be stored at temperatures below 30°C to prevent the growth of thermophiles. Because of the high safety implications and severe processing conditions, the conventional thermal sterilization has been accepted to result in considerable product quality degradation. However, many improvements have been implemented to improve thermal processing operations and techniques, and novel processing approaches have been introduced in recent years to improve the quality of thermally processed foods without compromising safety of these products. Therefore, the main focus of this chapter is to describe the basic principles of thermal processing operation in terms of production of safe and better quality products.

THERMAL PROCESSING BASICS

INTRODUCTION

The major objective of thermal processing is production of safe and stable products that consumers are willing and able to buy. To achieve this goal, it is necessary to understand the scientific basis on which the process is established. Silva et al. (1992) indicated that commercial thermal processing is a function of several factors, such as product thermo-physical properties (product heating rate), surface heat transfer coefficient, initial food temperature, retort temperature, heating medium (hot water or steam), heating medium come-up time (CUT), temperature resistance of food microorganisms and quality factors, and target degree of lethality or safety level we need to achieve.

The success of thermal processing does not depend on the elimination of the entire microbial population, because this would result in low product quality due to the long heating required. Instead, all pathogenic and most spoilage-causing microorganisms in a hermetically sealed container are destroyed, bulk of the spore formers is killed, and an environment is created inside the container that does not support the growth of remaining spore formers. There are different mechanisms that enable one to control the germination and growth of such type of spores in canned foods. These are based on the microbial growth and inactivation with respect to oxygen requirement, pH preference, and temperature sensitivity.

In general, canned foods have a 200-year history and are likely to remain popular in the foreseeable future owing to their convenience, long shelf life, and low cost of production. The technology is receiving increasing attention from thermal-processing specialists to improve both the economy and quality of some canned foods (Durance 1997). However, the sterilization process not only extends the shelf life of the food, but also affects its nutritional and sensorial qualities. Process optimization is therefore necessary in order to promote better quality retention without sacrificing safety.

REACTION RATE

During thermal processing of foods, several types of chemical reactions occur. Some reactions result in a quality loss and such type of reactions must be minimized, whereas others result in the development and formation of a desirable flavor, taste, or color, and these ones must be optimized to obtain the best product quality (Toledo 2007). In order to maintain quality of food products through optimization of processing conditions, predictive mathematical models are very important. To realize this goal, information is needed on the rates of destruction of microbes as well as quality parameters and their dependence on variables such as temperature, pH, light, oxygen, and moisture content, which can be expressed by mathematical models. A better understanding of kinetics of food products can provide better opportunities for developing food processes to maximize quality parameters and ensuring safety.

Each reaction undergoes on its own rate and the rate of reaction is described by the reaction kinetics. Kinetics is the study of the rate at which compounds react. Reaction kinetics (rate theory) deals to a large extent with the factors that influence the reaction velocity. The rate depends on several factors, including the contact between the reacting components, their concentration, temperature, and pressure at which the reaction takes place. The "collision theory" implies that the molecules need to collide with each other in order for the reaction to take place. If there are a higher number of collisions in a system, there is a greater chance for the reaction to occur. The reaction will go faster, and the rate of the reaction will be higher. In collision theory, two main things are to be considered: the activation energy, which

is the minimum energy required to initiate the collision, and the statistical probability for collisions between certain molecules that possess an adequate energy level for the reaction to occur at a given temperature. To measure a reaction rate, it is necessary to monitor the concentration of one of the reactants or products as a function of time. Therefore, the rate of reaction can be expressed as a rate of change in concentration to change in time.

On the basis of this concept, the rate law is an expression relating the rate of a reaction to the concentrations of the chemical species present, which may include reactants, products, and catalysts. Many food reactions follow a simple rate law, which takes the form

$$r = k[A]^a[B]^b[C]^c \qquad (1)$$

that is, the rate (r) is proportional to the concentrations of the reactants (A, B, C) each raised to some power. The constant of proportionality, k, is called the rate constant. The power a particular concentration is raised is the order of the reaction with respect to that reactant. Note that the orders do not have to be integers. The sum of the powers in Equation 1 is called the overall reaction order.

Zero-Order Reaction

A zero-order reaction is independent of the concentration of the reactants. A higher concentration of reactants will not speed up the zero-order reaction. This means that the rate of the reaction is equal to the rate constant, k, of that reaction. Zero-order reaction is described as

$$\text{Rate} = r = -\frac{dA}{dt} = k[A]^0 \qquad (2)$$

After separating variables and integrating both sides of Equation 2

$$\int_{A_0}^{A} dA = -\int_{t_0}^{t} kdt \qquad (3)$$

This provides the integrated form of the rate law

$$[A] = [A_O] - kt \qquad (4)$$

where k is the rate constant of the reaction, A is concentration at time t. In a zero-order reaction, when concentration data $[A]$ is plotted versus time (t), the result is a straight line.

First-Order Reaction

A first-order reaction is one where the rate depends on the concentration of the species to the first power. Most of the reactions involved in the processing of foods are of first-order reactions. For a general unimolecular reaction, the decrease in the concentration A over time t can be written as

$$\text{Rate} = r = -\frac{dA}{dt} = k[A]^1 \qquad (5)$$

Rearranging the equation

$$-\frac{dA}{A} = kdt \qquad (6)$$

Integrate both sides of the equation

$$\int_{A_0}^{A} \frac{dA}{A} = -\int_{t_0}^{t_0} kdt \qquad (7)$$

and the linear for of Equation 7 is:

$$\ln[A] = \ln[A_0] - kt \qquad (8)$$

where $[A]$ is the concentration at time t, $[A_0]$ is the concentration at time $t = 0$, and k is reaction rate constant (s^{-1}).

Plotting $\ln[A]$ with respect to time (t) for a first-order reaction gives a straight line with the slope of the line equal to $-k$, where the rate constant is calculated.

Second-Order Reaction

A second-order reaction is one where the rate depends on the concentration of the species to the second power. The reaction rate expression for a unimolecular second-order reaction is

$$\frac{dA}{dt} = -k[A]^2 \qquad (9)$$

Separation of variables and integration of both sides of equations will give us

$$\frac{dA}{[A]^2} = -kdt \qquad (10)$$

$$\int_{A_0}^{A} \frac{A}{[A]^2} = -\int_{t_0}^{t} kt \qquad (11)$$

$$\frac{1}{[A]} = \frac{1}{[A_0]} + kt \qquad (12)$$

Second-order unimolecular reaction is characterized by a hyperbolic relationship between concentration of the reactant or product and time. A linear plot will be obtained if $1/A$ is plotted against time.

Second-order bimolecular reactions may also follow the following rate equation:

$$A + B \rightarrow P$$

$$\text{Rate} = \frac{dA}{dt} = -k[A][B] \qquad (13)$$

where A and B are the reactants. After separating variables, the differential equation may be integrated by holding B constant to give

$$\frac{dA}{[A]} = -k[B]dt \qquad (14)$$

$$\int_{A_0}^{A} \frac{dA}{A} = -\int_{t_0}^{t_0} k'dt \qquad (15)$$

$$\frac{1}{[A]} = \frac{1}{[A_0]} - k't \qquad (16)$$

k' is a pseudo-first-order rate constant: $k' = kB$.

A second-order bimolecular reaction will yield a similar plot of the concentration of the reactant against time as a first-order unimolecular reaction, but the reaction rate constant will vary with different concentrations of the second reactant (Table 38.1).

Table 38.1. Summary of Zero-, First-, and Second-Order Reaction Rates (*M*-molar Concentration)

Rate Law/Order	Differential Form	Integral Form	Linear Plot to Determine k	Units of Reaction Constant (k)
Zero	$\dfrac{dA}{dt} = -k$	$[A] = [A_o] - kt$	*[A]* vs. t	$\dfrac{M}{s}$
First	$\dfrac{dA}{dt} = -k[A]^1$	$\ln[A] = \ln[A_o] - kt$	$\ln[A]$ vs. t	$\dfrac{1}{s}$
Second	$\dfrac{dA}{dt} = -k[A]^2$	$\dfrac{1}{[A]} = \dfrac{1}{[A_o]} + kt$	$\dfrac{1}{[A]}$ vs. t	$\dfrac{1}{M.s}$

COMMON FOOD MICROORGANISMS

Foods by their very nature involve complex biological molecules that strongly support the survival and growth of food microorganisms. One of the major causes for food deterioration is the growth and activity of microorganisms. Microorganisms can contaminate the food before and after processing from various sources. The major categories of microorganisms involved in food spoilage and deterioration are fungi and bacteria. Each microorganism has its own optimum temperature, pH, and oxygen level to grow. Broadly, food microorganisms can be categorized as pathogenic and spoilage ones. Food pathogenic microorganisms are those groups that can cause illness in human being or animals due to food poisoning or infection. Food poisoning and food infection are different, although the symptoms are similar. True food poisoning or food intoxication is caused by eating food that contains a toxin or poison due to bacterial or fungal growth in food. The bacteria or fungi that produced and excreted the toxic waste products into the food may be destroyed during processing, but the toxin they produced can cause the illness or digestive upset to occur. *Staphylococcus aureus* and *Clostridium botulinum* are two common species of bacteria that cause food poisoning. Food infection is the second type of foodborne illness. It is caused by eating food that contains certain types of live bacteria, which are present in the food. Once the food is consumed, the bacterial cells themselves continue to grow and illness can result. *Salmonellae, C. perifringens, Vibiro*

parahaemolyticus, Yersinia enterocolitica, and *Listeria monocytogenesis* are common infectious bacteria of food.

The other category includes food spoilage microorganisms. Food spoilage can be defined as the process or change leading to a product becoming undesirable or unacceptable for consumption. This can be chemical, physical, or microbial spoilage or the combination of these factors. Food spoilage is more of an economic concern than safety issue.

Food microorganisms can be grouped based up on their oxygen and temperature requirement for survival and growth (Table 38.2). In foods that are packaged under vacuum, low oxygen levels are intentionally achieved. Therefore, the prevailing conditions do not support the growth of microorganisms that require oxygen (obligate aerobes). Likewise, the thermophilic microorganisms require temperatures much higher than 30°C for their growth.

Acidity level of a food is another intrinsic food factor that determines the survival and growth of food microorganisms. From thermal processing standpoint, foods are divided into three pH groups: (i) high-acid foods (pH < 3.7), (ii) acid or medium-acid foods (3.7 < pH < 4.5), and (iii) low-acid foods (pH > 4.5). The most important distinction in the pH classification, with reference to thermal processing, is the dividing line between acid and low-acid foods. Most laboratories concerned with thermal processing have devoted attention to *C. botulinum,* which is a highly heat-resistant, rod-shaped, spore-forming, anaerobic

Table 38.2. Classification of Microorganisms and Bacteria Based on Their Oxygen Demand and Optimum Temperature for Growth

Classification Groups of Microorganisms	Examples of Microorganisms
Oxygen-based classification	
Obligatory aerobes (require oxygen)	Most molds, *Micrococcus, Serratia marcescens, Mycobacterium tuberculosis*
Obligatory anaerobes (require absence of oxygen)	*C. botulinum, C. sporogenes, C. thermosaccharolyticum*
Facultative anaerobes (tolerate some oxygen)	*Bacillus coagulans, Staphylococcus aureus*
Optimum temperature for growth	
Thermophilic (55–35°C)	*B. coagulans; S. thermophilus; C. thermosaccharolyticum, C. nigrificans*
Mesophilic (40–10°C)	*C. pasteurianum, B. mascerans, C. sporogenes, B. licheniformis*
Psychrophilic (35–<5°C)	*Pseudomonas, Micrococcus, C. botulinum* Type E, *S. aureus*

pathogen that produces the deadly botulism toxin. It has been generally recognized that *C. botulinum* does not grow and produce toxin below a pH of 4.5. Hence, the dividing pH between the low-acid and acid groups is set at 4.5. There may be other microorganisms that are more heat-resistant than *C. botulinum*.

THERMAL RESISTANCE OF FOOD MICROORGANISMS

As indicated in the above sections, the success of thermal processing depends on the destruction of all pathogenic and most spoilage-causing microorganisms in a hermetically sealed container and creating an environment inside the package that is not conducive to the growth of spoilage-type microorganisms and their spores that resist the thermal process. The microorganisms vary in terms of heat resistance and require different degree of thermal processing. In order to establish a thermal process, first, the target heat-resistant microorganisms of concern need to be identified. *C. botulinum* is the principle target microorganism of concern in low-acid canned foods. The second step is evaluating the thermal resistance of target organism. The thermal resistance data should be well described by an appropriate and reliable mathematical model. Data on the temperature dependence of the microbial destruction rate are also needed to integrate the destruction effect through the temperature profile under processing conditions.

KINETICS OF MICROBIAL DEATH

An understanding of the mechanism and kinetics of thermal death of food microorganisms would be helpful in the practical use of heat in processing of foods. Thermal destruction of bacteria is generally accepted to be exponential with time, and process calculations used in thermal processing are generally based on this assumption (Stumbo 1973). However, there are also nonexponential thermal death patterns indicated in different literatures (Stumbo 1973, Toledo 2007). The theory that thermal death of bacteria follows the first-order kinetics has been well recognized (Stumbo 1973). A first-order reaction is one in which the rate is proportional to the number of microorganisms present.

Decimal Reduction Time and Thermal Death Time

When a suspension of microorganisms is heated at constant temperature, the decrease in number of viable organisms follows logarithmic order of death. In other words, the logarithm of the surviving number of microorganisms following a heat treatment at a particular temperature plotted against heating time will give a straight-line curve (Fig. 38.1). These curves are commonly called survivor curves. The microbial destruction rate is defined as a decimal reduction time or *D*-value (minutes), which is the heating time in minutes at a given temperature required to result in one decimal or log unit reduction in the surviving microbial population. In other words, *D*-value represents a heating time that results in 90% destruction of the microbial population from the initial number. The rate of microbial destruction with time at constant temperature expressed as

$$\frac{dN}{dt} = -k[N]^1 \tag{17}$$
Figure 38.1. Survivor curve that depicts the number of survivor microorganisms versus time at a constant temperature.

where dN/dt is the change in microbial population with time t, k is the reaction rate constant, and 1 is to indicate the order of reaction (first order). After separation of variables and integration, the above equation can be written as

$$\ln N = \ln N_0 - kt \tag{18}$$

where N_0 is initial population of microorganisms.

D is based on common logarithms, in contrast with k, which is based on natural logarithms. But D and k are related as

$$\ln\left(\frac{N}{N_0}\right) = \ln(10)\log\left(\frac{N}{N_0}\right) = -kt \tag{19}$$

From this

$$\log\left(\frac{N}{N_0}\right) = -\frac{k}{\ln(10)}t \tag{20}$$

Thus, the D value is the negative reciprocal of the slope of a plot of $\log(N)$ against t, and D and k are related as

$$-\frac{1}{D} = -\frac{k}{\ln(10)}; \quad D = \frac{\ln(10)}{k} \quad \text{or} \quad D = \frac{2.303}{k} \tag{21}$$

Therefore, the D value from survivor curve can be expressed as

$$D = \frac{(t_2 - t_1)}{(\log N_0 - \log N)} \tag{22}$$

where N_0 and N represent the survivors following heating for t_1 and t_2 (minutes), respectively.

Commonly in thermal processing applications, survivor curves are plotted on specially designed semi-log papers for easy handling and interpretation data. The survivor number of microorganisms is plotted directly on the logarithmic *y*-axis against time on the linear *x*-axis. From this graph, the *D* value can be

Table 38.3. Probability of Residual Fraction Survivors after Multiple D Values

D Value ($N_o = 10^3$)	Probability of Residual Fraction Survivors After 90% of Destruction
$1D$	10^2
$2D$	10^1
$3D$	10^0
$4D$	10^{-1}
$5D$	10^{-2}
nD	10^{n-3}

Figure 38.2. Multiple D and TDT.

calculated from the time interval on x-axis between which the straight-line portion of the curve on the y-axis shows a reduction by logarithmic unit. For instance, as indicated in Figure 38.1 the number of survivor microorganisms is reduced from 100 (two logarithmic unit) to 10 (one logarithmic unit) in approximate time interval of 10 minutes (24–14 minutes), which is the D value at a given constant temperature. However, in today's computer era, the D value can be obtained from a log (N) versus t computer graph on a spreadsheet as the negative reciprocal slope. The logarithmic nature of the survivor curve indicates that complete destruction of microbial population is not theoretically possible; a decimal fraction of the population should remain even after an infinite number of D values (Table 38.3).

Thermal death time (TDT) is another concept that is commonly used in thermal processing of food. The concept somewhat contradicts the logarithmic destruction approach. As compared to decimal reduction concept, TDT is the minimum heating time required to cause complete destruction of a microbial population. In sequential study with microbial destruction as a function of time (at a given temperature), TDT then represents a time between the shortest destruction and the longest survival times. The difference between the two is sequentially reduced or geometrically averaged to get an estimate of TDT. The "death" in this instance generally indicates the failure of a given microbial population, after the heat treatment, to show a positive growth in the subculture media. Comparing the TDT approach with the decimal reduction approach, one can easily recognize that TDT value depends on the initial microbial load (whereas D value does not). Further, if TDT is always measured with reference to a standard initial load or load reduction, it would simply represent a certain multiple of D value. For example, if *TDT* represented the time to reduce the population from $N_0 = 10^2$ to $N = 10^{-1}$, then TDT is a measure of $3D$ values (Figure 38.2). On the other hand, if it is based on 10^4–10^{-6}, it would represent a $10D$ value. Therefore, TDT is a multiple of D (TDT $= nD$, were n is the number of decimal reductions).

Temperature Dependency of Kinetic Parameters

The D value (and TDT) is strongly dependent on the temperature applied during heating of bacterial suspension. Higher temper-

atures will give shorter D values and vice versa. Temperature dependency of kinematic parameters is expressed in terms of D-z or TDT-z models. By plotting the various D-values (or TDT) against temperature, again on a logarithmic scale, the z-value can be obtained as temperature range for the D-value (or TDT) curve to pass through one log cycle (Fig. 38.3). In this concept, the temperature sensitivity indicator is defined as the z value. Physically, z represents the temperature change need to increase or decrease the decimal reduction time (or TDT) by a factor of 10.
Figure 38.3. D value versus temperature curve and z value.

Mathematically, using reference temperature (T_r) and reference D value (D_0), z value (°C) is expressed as

$$z = \frac{T_r - T}{\log D - \log D_0} \tag{23}$$

or in between two temperature ranges of T_1 and T_2,

$$z = \frac{T_2 - T_1}{\log D_1 - \log D_2} \tag{24}$$

where D_1 and D_2 are D values at T_1 and T_2, respectively.

A larger z value indicates that the rate of destruction of microorganism is less temperature sensitive. A small z value indicates higher temperature sensitivity and a small change in temperature will result in a significant change on microbial population. Most commonly, quality parameters like nutrients and color have large z values as compared to microorganisms that have small z values. Again, microbial spores will have a higher z as compared to vegetative bacteria.

The D value at any given temperature can be obtained from a modified form of the above equation using the reference D value (D_0 at a reference temperature, T_r, usually 121.1°C (250°F) for thermal sterilization and 82.2°C (180°F) for pasteurization).

$$D = D_0 10^{\left(\frac{T_r - T}{z}\right)} \tag{25}$$

Concepts of Process Lethality

Lethality (F_0 value) is a measure of the heat treatment or sterilization processes. To compare the relative sterilizing capacities of heat processes, a unit of lethality needs to be established. For convenience, this is defined as an equivalent heating time of 1 minute at a reference temperature, which is usually taken to be 121.1°C (250°F) for the sterilization processes. The criteria for the adequacy of a process must be based on two microbiological considerations: (i) destruction of the microbial population of public health significance and (ii) reduction in the number of spoilage-causing bacteria.

In the canning industry, the F_0 value is often used for the low-acid canned foods and refers to the lethality value ($F_{T_{ref}}^{z}$ value) with a z value of 10°C (18°F) and a reference temperature (T_{ref}) of 121.1°C (250°F). The z value of 10°C is used as the thermal characteristic for the pathogenic microorganism, *C. botulinum* spores.

Experimental work and experience have shown that a process that achieves 12 log reductions of *C. botulinum* can be considered commercially sterile (Tucker 2008). If such a process is correctly applied to a product, then the health risk to the consumer will be insignificant. Applying a 12D process reduces the probability of spore survival by a factor of 10^{12}. If cans contain one initial spore, then for trillion cans produced and given a 12D process, only one can would contain a surviving spore.

The $D_{121.1°C}$ ($D_{250°F}$ or D_0) value can be used for establishing such a process. The D_0 for *C. botulinum* is taken as 0.23 minute. Thus, 12D value would represent 12×0.23 or 2.76 minutes. The minimum F_0 value should be 2.76 minutes to accomplish the 12D process. In general, if N_0 is the initial spore concentration and N the target spore concentration need to achieve, then for exposure to a theoretical constant process temperature

of 121.1°C at the coldest or slowest heating point, the target process would be:

$$F_0 = D_0 \log\left(\frac{N_0}{N}\right) \tag{26}$$

However, several low-acid foods are processed beyond the minimum F_0 value of 2.76 minutes in order to deal with spoilage-causing bacteria of much greater heat resistance. For these organisms, acceptable levels of spoilage probability are usually dictated by economic considerations. Most food companies accept a spoilage probability of 10^{-5} ($5D$ = TDT) from mesophilic spore formers (organisms that can grow and spoil food at room temperature). The organism most frequently used to characterize this classification of food spoilage is a strain of *C. sporogenes*, known as PA 3679, with a maximum $D_{121.1°C}$ value of 1.00 minute. Therefore, the $5D$ minimum value would be 5 minutes and hence a F_0 of 5 minutes is more commonly used for these foods. Where thermophilic spoilage is a problem, more severe processes may be necessary because of the high heat resistance of thermophilic spores. Fortunately, most thermophiles do not grow readily at room temperature and require incubation at unusually high storage temperatures (>38°C) to cause food spoilage.

Sterilization time required at temperature (T) for the same value target microorganism to deliver equal degree of sterility is mathematically expressed as

$$F_T^z = F_0 * 10^{\left(\frac{T_{ref} - T}{z}\right)} \tag{27}$$

The same general relationships as were discussed under sterilization apply to pasteurization. A combination of temperature and time that is sufficient to inactivate the particular species of bacteria must be used. Fortunately, most of the pathogenic organisms, which can be transmitted from food to the person who eats it, are not very resistant to heat. For thermal process calculation of high-acid canned foods with an extended refrigerated shelf life, for shelf-stable low pH < 3.9 products (such as fruit juices) and acidified foods under normal storage conditions, food industries commonly use the pasteurization value (P_o with z value of 10°C and T_{ref} of 82.2ºC) instead of the sterilization value (F_o value), since foods generally are processed below or around 100°C.

THERMAL PROCESS DETERMINATION METHODS

Thermal process evaluation is a process of determining the desired processing time at a given heating condition to achieve desired process lethality or vice versa. Determination of process lethality (F_0) can be done in two ways: using calculation method (Equation 27) and microbiological data (Equation 26). Different calculation methods have been used to determine the required processing time to achieve the desired lethality. The reliability of the method depends on how accurately it integrates the lethality effect of transit temperature response of the food undergoing thermal process, with respect to test microorganism of public health concern. This implies that accurate determination

of microbial kinetic data and reliable measurement of temperature profile of the product at the worst case or slowest heating point within the container are important inputs to determine or evaluate the reliability of a given thermal process.

The desired degree of lethality in terms of minimum equivalent time at a given reference temperature is generally preestablished for a given product considering kinetic data of target microorganism, and processes are designed to deliver a minimum of this preset value at the thermal center. There are essentially two widely accepted categories of methods for using these data to perform thermal process calculations. The first of category is the General Method of process calculation based on Bigelow et al. (1920) method of calculation, and the second is the Formula Method of process calculation based on concepts of Ball (1923) or Stumbo (1973).

GENERAL METHOD

The General Method developed by Bigelow et al. (1920) is a graphical procedure to calculate thermal processes. It is a simple method and can be applied to any product and process situation. The method is used to determine sterility equivalents at known product temperatures measured directly by the use of thermocouples positioned within the slowest heating test container at the slowest heating spot in the container. It is the most accurate method for evaluating under a given set of heat penetration data gathering. It is universally applicable to essentially any type of thermal processing situation and used to get the baseline target value upon which all other experimental and formula calculation method performances are compared.

However, the time–temperature data is at the coldest spot and the method is only used to calculate process times for the given heat profile data. Because of this main limitation of the method, it lacks predictive power for different processes. There are two General Method approaches: Original General Method and Improved General Method.

Original General Method

The Original General Method uses the time–temperature data at slowest heating point of the product and converts this data to destruction rate graph to determine sterilization value of the process (area under the curve in the graphical procedure). The procedure is to plot the inverse of TDT against time to produce a destruction rate curve. The area beneath the curve corresponds to the accumulated sterilization value delivered by the process during heating and cooling (Fig. 38.4). Conversion of available time–temperature data to destruction rate is done using Equation 27. From gathered time–temperature data, TDT is calculated and then the reciprocal of TDT (TDT^{-1}) is computed for corresponding temperature (Table 38.4 columns 3 and 4). The reciprocal of TDT is known as the destruction rate achieved at that particular time–temperature combination. Using destruction rate versus time (1/TDT vs. Time), the graph is drawn and the area under the curve is determined by counting the squares, or using planimeter. A unit of sterilization area on the curve is equal to the product of destruction rate and time of unity, which is the minimum processing requirement to achieve desired degree of commercial sterilization value (SV) with respect to target microorganism. The sterilization value of the overall process can be calculated by considering the area under the curve divided by the unit sterilization area.

Graphical method of process calculation is summarized in Table 38.4 for *C. botulinum* with D_0 value of 0.21 minute to achieve TDT value of 12 D_0 (F_0) with z value of 18°F.

In order to get a target sterilization value, the process (steam off) time is appropriately increased or decreased, as the case may be by shifting cooling curve to right or left direction on
Figure 38.4. Graphical approach of process calculation. Broken lines are parallel lines drawn to the left after carrying out over-processing in order to get desired SV.

Table 38.4. Process Calculation by General Graphical and Numerical Integration Method

Time (min)	Temperature (°F)	$F = TDT = F_o * 10^{(Tr-T/z)}$	$1/TDT$	$1/TDT * \Delta t$

56	137	4.78E+06	2.1E−07	8.4E−07
60	97	7.97E+08	1.3E−09	5.0E−09
			SV = Σ(1/TDT)Δt =	**6.27**

a trial-and-error basis until the desired lethality achieved. In other words, this whole process is repeated until the desired SV is obtained, and the corresponding processing time is known. From food safety point of view and commercial processing conditions, the SV should be more than unity to ensure complete destruction of pathogens and reduction of spoilage microorganisms to the level that do not cause spoilage in postprocessing duration.

However, this graphical method is a tedious and cumbersome approach and requires a graphical trial-and-error works. Because of this reason, several approaches have been attempted to develop a simple approach in order to get similar information from gathered time–temperature data. One of the methods is the numerical integration method (Tabular Method) proposed by Patashnik (1953) (Table 38.4 column 5). In this method, the corresponding SV of each temperature is numerically calculated for each time interval, and the total SV is obtained for equal (Equation 28) and unequal (Equation 29) interval of time.

$$\text{Sterilization value} = \sum \left(\frac{1}{TDT}\right) \Delta t \qquad (28)$$

$$\text{Sterilization value} = \sum \left(\frac{1}{TDT}\Delta t\right) \qquad (29)$$

In Table 38.4, we obtained a SV of 6.14, which can be interpreted that the given heat treatment is 6.14 times more than what is required to destroy a given target microorganism. This is definitely an overprocessing and will have an impact on the quality of the product. Therefore, SV of 6.14 should be reduced to the value close to unity in order to achieve the desired degree of lethality of target microorganism.

Improved General Method

Like the original graphical approach, this method also requires heat penetration data and the conversion of product temperature to lethal rate. For the development of Improved General method, the two main contributions of Ball (1928) played a significant role. The first important point was the construction of a hypothetical reference TDT curve passing through 1 minute at reference temperature of 121.1°C (250°F) having a given z value. In addition to this, Ball (1928) introduced the term lethal rate (L) for a given temperature according to the following Equation 30 on the basis of Equation 27.

$$\frac{F_T^z}{F_0} = 10^{\left(\frac{T_{ref}-T}{z}\right)} \qquad (30)$$

For commercial sterilization process, the numerator on left side of Equation 30 indicates TDT at temperature T, which is equivalent to thermal treatment of 1 minute at reference temperature of 121.1°C (250°F) ($F_{T_{ref}=121.1°C}^{z=10}$). Therefore, based upon this concept, Equation 30 can be written as

$$\frac{F_T^z}{1} = 10^{\left(\frac{T_{ref}-T}{z}\right)},$$

where $F_T^z = TDT_T$ and after rearranging, we get

$$\frac{1}{TDT_T} = L = 10^{\left(\frac{T_r-ref}{z}\right)} \qquad (31)$$

The left-hand side term refers lethal rate (L) and L is calculated as a function of temperature versus time from heat penetration data at a specific temperature. The lethal effects at the different time–temperature combinations in a thermal process are integrated so as to account for the total accumulated lethality, since each temperature is considered to have a sterilizing

Table 38.5. Example of Improved General Method for Process Evaluation at Reference Temperature of 250°F and *z* Value of 18°F

Time (min)	Temperature (°F)	Lethality Rate (min) $L = 10^{(T-Tr/z)}$	Accumulated lethality (min) $L * \Delta t$

Accumulated lethality = 15.80

value during the entire heating and cooling phases (Equation 32; Table 38.5).

$$\text{Accumulated lethality} = F_0 = \int_0^t 10^{\left(\frac{T-T_r}{z}\right)} dt = \int_0^t$$

$$L = \sum_0^t L\Delta t \tag{32}$$

Note that general methods do not have any specific requirement about the shape of the time–temperature curve. They are therefore accurate and they should be the methods of choice for handling "complex" temperature data (Ball 1928). In 1980s, computerized mathematical models for predicting time–temperature data using improved general method were developed by different researchers (Teixeira and Manson 1982, Datta et al. 1986, Sastry 1986, Chandarana and Gavin 1989, Chang and Toledo 1989, Lee et al. 1990) for F_0 value calculations.

Even though the General Method is the base for comparing the accuracy of other formula methods, the process is critically dependent on product, container, and process delivery system conditions as studied at the time of the test. Extrapolation outside the given process condition yields undefined, invalid lethality results. Additional testing must be performed to verify the sterilizing value delivered under the altered conditions.

FORMULA METHODS

The formula method of process calculation simplifies the tedious steps associated in calculating process time using general methods. However, it requires characterization of the nonlinear heat penetration data to compute the key heat penetration parameters.

Characterization of Heat Penetration Data

Heat penetration data are time–temperature combination data that are collected after exposing a given food for a given period of time under a given heating condition. For products in metal cans, which are mainly heated by conduction, the slowest heating point is the center of the container, and for products whose mode of heating predominated by convection, the slowest heating point is 1/10th above the bottom of the can along the central vertical axis. Accurate determination of heating profile of a given system is very important for accurate establishment of process schedule. The profile should be collected under conditions that simulate the actual process situations. Typical heat penetration profiles for conduction and convention heating products is shown in Figure 38.5.

Because of the limitations of the General Method, a more robust Formula Method was developed and proposed by Ball (1923). It makes use of the fact that the difference between retort and cold spot temperature decays exponentially over process time after an initial lag period. Therefore, a semi-logarithmic plot of this temperature difference over time appears as a straight line that can be described mathematically by a simple formula and related to lethality requirements by a set of tables that must be used in conjunction with the formula. The originally developed method was later modified by Ball and Olson (1957), which has been still widely used in the canning industry.
Figure 38.5. Heat penetration curves foods in container in relation to retort temperature ($\Diamond$), convective heating ($\blacksquare$), and conductive heating ($\blacktriangle$).

Equation 33 derived from the heat penetration curve is used to estimate the process time, B (minutes).

$$B = f_h \log \frac{j_h I_h}{g} \tag{33}$$

In order to understand the contents of this equation and determine the process time (B), it is necessary to recognize heat penetration parameters, retort CUT, other several inputs, and assumptions of Ball (1923) as indicated in the following section.

Heat Penetration Parameters

The following data are normally obtained from the heat penetration data and heating conditions for calculation purposes as well:

f_h—Heating rate index. It is the time required for the straight-line portion of the heating curve to pass through one log cycle. It is also the negative reciprocal slope of the heating rate curve.

j_h—Heating rate lag factor. This is a factor that, when multiplied by I_h, locates the intersection of the extension of the straight-line portion of the semi-log heating curve and the vertical line representing the effective beginning of the process (0.58 CUT).

$$j_{ch} = \frac{T_r - T_{pih}}{T_r - T_{ih}} \tag{34}$$

I_{ih}—Difference between the retort temperature and food temperature at the start of the heating process ($T_r - T_{ih}$).

T_r—Retort temperature.

T_{pih}—Pseudo-initial temperature during heating. It is the temperature indicated by the intersection of the extension of the heating curve (original T_{pih}) and the vertical line representing the effective beginning of the process (0.58 CUT) (New T_{pih}).

T_{ih}—Initial food temperature when heating is started.

CUT—Come-up time. In batch processing operations, the retort requires some time for reaching the operating condition. The time from steam on to when the retort reached T_r is called the CUT.

0.58 CUT—Effective beginning of the process. Implies 58% of CUT from the start, which do not significantly contributes for process lethality. Ball recognized that the last 42% of the CUT only has a significant contribution on sterilization process.

g—Difference between the retort temperature (T_r) and the maximum temperature (T) reached by the food at the slowest heating point ($T_r - T$).

T_{ic}—Food temperature when cooling is started.

T_{cw}—Cooling water temperature.

I_c—Difference between the cooling water temperature and food temperature at the start of the cooling process ($T_{ic} - T_w$).

g_c—The value of g at the end of heating or beginning of cooling ($T_r - T_{ic}$).

f_c—Cooling rate index. The time required for the straight-line portion of the cooling curve to pass through one log cycle. It is also the negative reciprocal slope of the cooling rate curve.

T_{pic}—Pseudo-initial temperature during cooling. It is the temperature indicated by the intersection of the extension of the cooling curve and the vertical line representing the start of cooling.

j_{cc}—Cooling rate lag factor. This is a factor that, when multiplied by I_c, locates the intersection of the extension of the straight-line portion of the semi-log cooling curve and the vertical line representing the start of the cooling process.

$$j_{cc} = \frac{T_{cw} - T_{pic}}{T_{cw} - T_{ic}} \tag{35}$$

Formula methods make use of heat penetration data obtained from a semi-logarithmic plot of the temperature difference ($T_r - T$) on log scale against time (on linear abscissa). When the temperature difference is greater than one, three-cycle log paper is recommended (Fig. 38.6), and when the difference is below one, four-cycle log paper is required.

Gathered time–temperature data may be plotted in two different ways. In the first case, log ($T_r - T$) versus time is plotted on the paper (spread sheet), and the slope is obtained from the linear portion of the negative reciprocal slope of the graph. The lag factor is calculated from the intercept of the equation of the line. In the second case, the semi-log paper is rotated 180° (Jackson plot) and the top line of the paper is marked 1° less than retort temperature ($T_r - 1$°C), the next log cycle is marked 10° less ($T_r - 10$°C), and then the third cycle 100°C less ($T_r - 100$°C). Using this interval, the product temperatures are directly numbered without conversion on semi-log graphing paper to produce the linear plot needed to determine heating rate index (f_h) and lag factor (j_h) (Fig. 38.7).

The Retort CUT, f_h and j_h Values

Once heating medium (hot water or steam) is injected into the retort, the retort is not reached immediately to the specified operating temperature of 121.1°C. The time from introduction of
Figure 38.6. Diagram showing how the axis of semi-logarithmic graphing paper (rotated 180°C) is marked for plotting heat penetration data for retort temperature of 121°C.
Figure 38.7. Heat penetration curve on semi-log paper during heating phase.

heating medium to when processing temperature (T_r) is reached is the retort CUT. Among his several assumptions, Ball (1923) assumed that 58% of the retort CUT has no significant heating or lethality value; therefore, heating starts from a pseudo-initial time (t_{pih}), which is 058% of CUT (0.58 CUT). According to Figure 38.7, the total CUT is assumed as 12 minutes. Therefore, the corrected zero time or pseudo-initial time (t_{pih}) is 7 minutes (0.58∗12). From hypothetical data of Figure 38.7, the heating parameters of j_h and f_h are

$$j_h = \frac{T_r - T_{pih}}{T_r - T_{ih}} = \frac{121 - 61}{121 - 71} = 1.2 \quad \text{and,}$$
$$f_h = 74.4 - 14.4 = 60 \text{ minutes}$$

The heating rate index (f_h−value) is obtained as the time for the curve to traverse one logarithmic cycle (Fig. 38.7).

For cooling part, to plot the cooling curve on semi-log paper (in this case you do not need to rotate 180°), the bottom line is marked 1°C, the second log cycle 10°C, and the third log cycle 100°C above the cooling water temperature (Figure 38.8). Then, temperatures are plotted directly on the y-axis of semi-log paper and time of cooling on x-axis. Cooling parameters, f_c and j_{cc}, (Equation 35) are obtained likewise during heating, except there are no come-down time considerations during cooling.

In addition to this, the cooling curve can be obtained by plotting a cooling curve graph from log difference of temperature of a product to that of cooling water temperature ($\log(T - T_{cw})$)
Figure 38.8. Heat penetration curve on semi-log paper during cooling phase.

versus time. The beginning of cooling time (time zero) is considered the end of heating time. The cooling rate index (f_c) is calculated from the negative reciprocal slope of cooling curve and the cooling lag factor (j_{cc}) from the intercept of the equation.

Ball calculated the process time based on straight-line equation of heating curve and integrating the effect of process time over the kinetic data of microbial destruction. He developed tables (Table 38.6) and graphs to relate process time and process

Table 38.6. f_h/U Versus Log g Values for the Ball Method

1.4	0.042	70	1.318
1.5	0.097	80	1.336
1.6	0.146	90	1.352
1.7	0.183	100	1.365
1.8	0.229	120	1.388
1.9	0.265	140	1.406
2	0.298	160	1.422
3	0.525	180	1.435
4	0.655	200	1.447

lethality. These were based on relating two parameters: g (temperature difference between heating medium and product at the end of heating) as a measure of process time and f_h/U (ratio of heating rate to sterilization value) as the measure of process lethality.

The lag factor for cooling cycle is important, because a significant contribution of sterilization takes place during the early part of the cooling period. Ball (1923) assigned a value of 1.41 for j_{cc} and also assumed $f_h = f_c$ so that the needed information can be obtained just from the heating curve. The values for f_c tend to be larger f_h because of the slower heat transfer with water compared to steam. Considering these factors, Ball related dimensionless ratio f_h/U versus g and expressed their relationship in the form of tables and figures. With the above assumptions, and experimentally obtained heating parameters (f_h, j_{ch}, I_{ch}), process calculations can easily be accomplished. Table 38.7 is an illustration of how process time (B) can be calculated. It can be seen it is necessary to get the input from Table 38.7 for finding the value of log g from f_h/U. As discussed before, the retort does not reach the desired retort temperature immediately after the steam is turned on, rather needs a finite heating time to come to operating temperature (CUT). On the basis of the assumed 42% effectiveness for the CUT, the operator's process time (P_t) is obtained from the Ball process time (B) (Equation 36).

$$B = P_t + 0.42\text{CUT} \tag{36}$$

The operator's process time P_t is the time interval from the time the retort reaches the desired process temperature to the time the steam is turned off. The CUT correction concept is only applied in Formula Methods, because in General Methods, the effect of the length of the CUT will be automatically included in the calculated lethality value because all the temperatures used in the calculation will reflect the effect of heat flowing into the product during the CUT. The stepwise procedure for calculating process lethality using Ball formula method is shown in Table 38.8.

Stumbo's Method

Stumbo's f_h/U versus log g tables (Stumbo 1973) includes the contribution from both the heating and cooling lags. These tables were developed after considering some restrictive assumptions made by Ball (1923).

Generally, the Formula Method assumptions were

1. Ball assumed a constant hyperbolic lag factor of 1.41 ($j_{cc} = 1.41$) for the cooling conditions, which is not the same in many cases. Early part of the cooling curve contributes significantly to the process lethality and hence j_{cc} is very important. Stumbo and Longley (1966) published tables that considered variations in cooling lag factor instead of assuming it to be constant (Table 38.9).
2. This is one of the assumptions made by Ball (1923) assuming the heating rate is equal to cooling rate during thermal processing time at the slowest heating part. Commonly under practical condition $f_h < f_{cc}$, which is more

Table 38.7. Procedure in Calculation of Process Time Using Ball Method for Conductive Heating Food

		Process Time Calculation
1	j_h	1.41

10	Log $(j_h{}^*I_h)$	2.024
11	$F_i = 10^{\left(\frac{250 - T_r}{z}\right)}$	$1.9 = 10^{\left(\frac{250-245}{18}\right)}$
12	$f_h/U = f_h/(F_o{}^*F_i)$	$f_h/U = 60/(1.9{}^*5) = 6.32$
13	Log g	From Ball Table 38. 6 by interpolation $= 0.821$
14	Log$(j_h.I_h) - \log g$	$1.203 = 2.024 - 0.821$
15	$B = f_h\ [log(j_h{}^*I_h) - log\ g)]$	72.18 min $= 60{}^*1.203$
16	$Pt = B - 42\%\ CUT$	68.82 min $= 72.18 - 0.42{}^*8$

conservative assumption from safety point of view but from quality point of view it has an over processing effect. In practice, most of the heating is done with steam or agitated water, while cooling is normally done in slowly circulating water. Therefore, generally $f_h < f_c$ and $f_h = f_c$ gives a more conservative processing conditions.

3. The temperature difference between the retort temperature and cooling water temperature $(T_r - T_{cw})$ is the driving force. This is expressed in terms of I_c, which is $(I_c = T_{ic} - T_{cw})$. Ball assumed that the sum of $I_c + g = T_r - T_{cw} = 180°F$ (for steam) or 130°F (for full immersion water overpressure). Stumbo (1973) discovered that, a 10°F change in $T_r - T_{cw}$ can result in 1% difference in calculated lethality (F_0) and can be corrected if required.

4. CUT correction for j_h value. Ball noticed that only about 42% of the CUT can be considered as effective contribution to the process time.

5. No further product heating after cooling starts. However, this is not always valid for the critical point of conduction in heated canned foods. In such cases, considerable overprocessing can occur.

Table 38.8. Calculation of Process Lethality Using Ball Method From Hypothetical Given Data

		Process Time Calculation
1	j_h	2.05
2	f_h	34.9 min
3	CUT	8 min
4	Pt	45 min
5	Process time $(B = Pt + 42\%CUT)$	$B = Pt + 42\%\ CUT$ $B = 45 + 0.42{}^*8 = 48.36$ *min*
6	Retort Temperature (T_r)	260°F
7	Initial temperature(T_i)	100°F
8	$I_{ch} = Tr - Ti$	160 °F $= 260 - 100$
9	$j_h{}^*I_{ch}$	328 °F $= 2.05\ {}^*160$
10	log $(j_h{}^*I_h)$	2.52
11	z value	18°F
12	$F_i = 10^{\left(\frac{250 - Tr}{z}\right)}$	0.278
13	B/f_h	$1.39 = 48.36/34.9$
14	log $g = \log(j_h{}^*I_h) - B/f_h$	log $g = 1.13 = 2.52 - 1.39$
15	f_h/U	From Ball Table 38.6 by interpolation $= 22.4$
16	$F_o = \frac{fh}{(fh/U*F_i)}$	$F_o = 34.9/(22.4\ {}^*0.278) = 5.60$ min

6. Also, the Stumbo method accommodates different values of z and can be used for not only cold-point values but also for integrated lethality computations. The use of this yield more accurate process times (Smith and Tung 1982).

Typical calculations of process time and process lethality using Stumbo method are illustrated in Tables 38.10 and 38.11.

QUALITY OPTIMIZATION

The effect of the thermal sterilization process on quality and nutrient retention of food has been of major concern for food processors since the invention of canning. During sterilization of foods, heat has two simultaneous effects: sterilization and cooking. Therefore, it is necessary to optimize between these

Table 38.10. Calculation of Process Time (B) Using Stumbo Method

1	j_h	0.96
2	f_h	12.6 min
3	Process lethality (F_o)	5 min
4	Retort temperature (T_r)	245°F
5	Initial temperature (T_i)	175°F
6	$I_h = T_r - T_i$	70°F = 245−175
7	$j_h{}^*I_h$	67.2
8	$\text{Log}(j_{ch}{}^*I_h)$	1.75
9	Z value	18°F
10	$F_i = 10^{\left(\frac{250-T_r}{z}\right)}$	1.9
11	$f_h/U = f_h/(F_o{}^*F_i)$	1.33
12	j_{cc}	1.6

From Stumbo's table for $z = 18°F$ (18°F) ($j_{cc} = 1.6$), obtain g value by interpolation

f_h/U	g value
1.00	0.638
1.33	?
2.00	2.34

Interpolated g value is 1.2 for f_h/U value of 1.33

13	$log\ g$	0.0792
14	$B = f_h\ [log\ (j_{ch}\ I_h) - log\ g)]$	21.68 min

Table 38.11. Calculation of Process Lethality (F_0) Using Stumbo Method

1	j_h	1.9
2	f_h	36.2 min
3	Operator process time (P_t)	42 min
4	CUT	10 min
5	Retort temperature (T_r)	255°F
6	Initial temperature (T_i)	160°F
7	$I_h = T_r - T_i$	95°F
8	$j_{ch}{}^*I_h$	180.5
9	$\text{Log}(j_{ch}{}^*I_h)$	2.26
10	z value	18°F
11	$F_i = 10^{\left(\frac{250-T_r}{z}\right)}$	0.53
12	$B = P_t + 42\%\ CUT$	46.2 min
12	B/f_h	1.28
13	$log\ g = log(j_{ch}{}^*I_h) - B/f_h$	0.98
14	g	9.55
15	j_{cc}	0.8

From Stumbo's table for $z = 18°F$ ($j_{cc} = 0.8$). Obtain f_h/U value by interpolation

f_h/U	g value
10.00	8.24
?	9.55
15.00	10.16

Interpolated f_h/U value is 13.41 for g value of 9.55

16	$F_0 = f_h/[(f_h/U)^*F_i]$	5.1 min

two effects to get a better quality safe product. This goal can be achieved by optimizing thermal process conditions. In order to achieve proper process optimization, accurate determination of kinetic parameters of microorganisms, spoilage enzymes, and quality factors are crucial. The need to optimize processing conditions arises when the kinetic behavior of the different components is considered because the rate of a chemical reaction generally doubles for a 10°C rise in temperature, whereas rates of bacterial destruction increase tenfold under similar conditions (Holdsworth 1985). Gathered kinetic parameters are used to develop reliable predictive models that will ensure to produce better quality products without compromising food safety.

There are two key issues that should be explored to produce better-quality safe products. The first choice may focus on reducing thermal intensity levels, through reducing of the heating, and cooling times associated with the process through improving heat transfer property of processing condition and modification of geometry of packaging material. The other option is to look for novel thermal or nonthermal food processing technologies that will ensure better quality products with relatively same degree of safety. New preservation technologies are utilized because of their expected potential to inactivate microorganisms and spoilage enzymes with a very little damage on product quality.

HIGH-TEMPERATURE SHORT-TIME AND ULTRA-HIGH TEMPERATURE PROCESSING

As the names implies, high-temperature short-time (HTST) and ultra high temperature (UHT) processes use higher temperatures and shorter processing times than conventional thermal processes to improve quality of foods and beverages. Because the products are exposed to high temperatures for short times, there is reduced degradation of quality factors of the products while causing a greater effect on destruction of food microorganisms.

The principle of HTST or UHT process is easily understood by comparing the heat resistance of nutrient components, microbial spores, and vegetative bacteria (Figure 38.9). The D value at reference temperature for vegetative bacteria are in fraction of seconds ($z = 5°C$); microbial spores, 0.2 minute ($z = 10°C$); and nutrient components, 100–150 minutes ($z = 25-30°C$). This variation gives an opportunity to optimize processing condition for better quality production of foods and beverages.

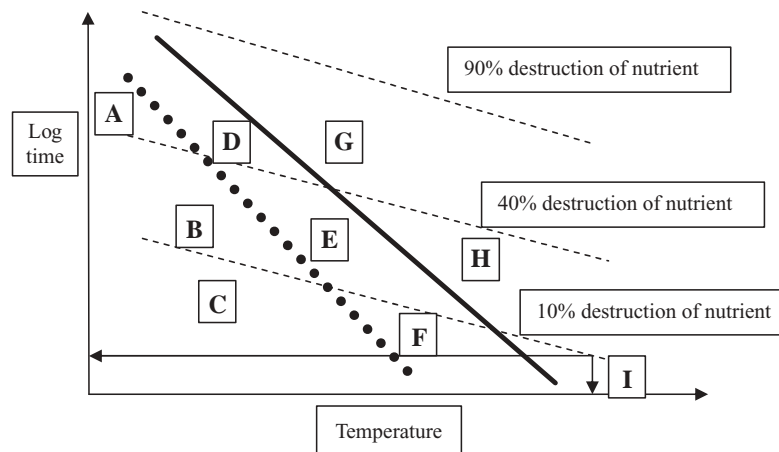
From destruction of vegetative bacteria point of view, area (A, B, and C) beneath the dotted line of the graph are not acceptable (Figure 38.9). In these sections, the vegetative bacteria are not yet destroyed. The same is true for section D, E, and F, where the product is cooked but spore formers still survive the heat treatment. All sections of G, H, and I above the bold line gives sterile product. However, the question that comes here is that, to what extent the product is cooked with respect to the quality factors. The top and bottom broken D lines represent 90% and 10% destruction of a nutrient component, respectively. Particularly, section I of the graph gives a safe product with less than 10% destruction of nutrient. This is the region corresponding to HTST or UHT treatment as indicated by the arrows.


Figure 38.9. A diagram of resistance of nutrient (- - -), microbial spores (–), vegetative bacteria (•••), and HTST heating principle.

For instance, in UHT sterilization process, milk is exposed for 2–5 seconds at high temperatures of 140–145°C to kill bacteria spores. UHT treatment limits browning of the milk, development of cooked flavor, and denaturation of proteins. In HTST pasteurization, milk is subjected to a temperature of 71.1°C for 15–20 seconds. HTST or UHT approaches are not always beneficial for conduction heating food products that heat relatively slowly, exhibiting large temperature gradients between surface and center of the container. However, they are best for liquid foods and liquids containing small particles that can heat rapidly while subjected to in-container thermal processing or in-heat exchangers, as an aseptic processing.

AGITATION PROCESSING

Some retorts agitate the cans during processing in order to increase the rate of heat penetration in cans. As compared to static retorts, the process time may be reduced by 80% because the contents are heated up faster and more evenly. Agitation processing is mainly groped into axial and end-over-end (EOE) type (Fig. 38.10). EOE involves the containers being loaded vertically and a crate rotating around a central horizontal axis. During axial rotation, cans are rotated individually in the horizontal plane.

As the containers are agitated inside a retort, the contents of the containers are mixed uniformly; this eliminates cold spots and increase heat penetration rate. Mixing largely is due to the movement of the headspace bubble during agitation, and to be effective, there must be sufficient headspace in cans. Both small and large headspace may result in lower heat transfer, leading to underprocessing because of limitation of mixing of food components in cans. In addition to headspace, fill of the container, solid to liquid ratio, consistency of the product, and the speed of agitation are the crucial factors to be standardized in agitating processing. Unless and otherwise these conditions are properly optimized for a given product and processing condition, the required fast heat penetration may not be achieved.

ASEPTIC PROCESSING

The word "asepsis" implies the process of removing pathogenic microorganisms or protecting against infection by such organisms. It can be defined as a state of control attained by using an aseptic work area and performing activities in a manner that precludes microbiological contamination of the exposed sterile product. In food processing, aseptic processing involves a section that precludes microbiological contamination of the

Cans in vertical position   **Cans in horizontal position**
Figure 38.10. End-over-end and axial agitation orientation of cans in retort cage.

final sealed product. During aseptic processing, the product is exposed to desired treatment temperature to eliminate food microorganisms and finally packed in sterile container in an aseptic environment. This processing method is more efficient for liquid products and liquid products containing small particles. Aseptic processing sterilizes food and beverages in a way that puts the least amount of thermal stress on a product, so nutrients and natural flavors, colors, and textures are maintained while sterility is ensured.

The aseptic process begins with sterilization of both the processing system and the filler. Generally, this is done with hot water or saturated steam. Food is then pumped into the aseptic processing system for sterilization. The flow of food is controlled via a timing pump, so that no food flows too fast or too slow.

This process consists of heating, holding, cooling, and packing steps. First, the product is heated and held for some time to attain desired degree of sterilization. Once the food leaves the hold tube, it is sterile and subject to contamination if microorganisms are permitted to enter the system. The best way to keep the product sterile is to keep it flowing and pressurized. Heating step is followed by cooling of the product. The next step is moving the product into an aseptic surge tank to hold the product just before packaging. Meanwhile, the packaging material is sterilized from the other side of the aseptic environment. Packaging material is sterilized by liquid hydrogen peroxide at a high temperature. After the food and package are sterilized, the sterile package is filled with the food, closed, and sealed in a sterile chamber.

The direct and indirect heating processes used in aseptic packaging can affect the final taste of the food. Indirect heating, the food comes into contact with either a metal plate or tube, which can give food, such as milk, a burnt flavor. There are three types of indirect heating processes: plate heat exchangers, tubular heat exchangers, and scraped-surface heat exchangers. The former two are mainly used for liquid foods and the latter one is for more viscous and particulate foods to prevent fouling due to high temperature effect. All use a physical separation between the product and the heating medium and transfer heat through either a plate or tube to the product.

Direct heating uses steam injection or steam infusion and minimizes the burnt flavor of the product by letting the food come into direct contact with the heat source. With steam injection, product and steam are pumped through the same chamber; while with steam infusion, the product is pumped through a steam-filled infusion chamber. In all these heat exchangers, since the product is directly exposed to heating medium or subjected to thin profile mode of heating, it allows faster heat penetration within short period of time, which destroys microorganisms with limited effect on quality of the product. That is why aseptic processing is considered as HTST processing in terms of optimization of quality with desired degree of safety. However, for particulate foods, the rate of heat penetration in the center of the slowest heating point of the product should be determined to ensure desired degree of pasteurization/sterilization. In particulate foods, first the heat is exchanged between the heating medium and liquid food, and then transferred to the particle. In this case, it is difficult to measure the temperature of the moving particle.

The time–temperature profile in the particle can be estimated using mathematical models. Based upon the data of the model used, the particle should be held at appropriate temperature for sufficient time to achieve the required sterilization value at the center.

THIN PROFILE AND RETORT POUCH PROCESSING

Quality optimization is mainly achieved through enhancing the heat transfer rate from the heating medium to the product. Any resistance to rapid heat penetration slows down the heat penetration rate and exposed the product for longer heating time. The nature of packaging material, thickness, and its overall thermal conductivity determine the heat transfer rate. In conventional thermal processing, metal cans and glass containers are the main type of containers used. However, the thickness of these containers limits fast transfer of heat between heating medium and product. Modification of geometric configuration of the packaging materials from material thickness and geometry point of view is additional opportunity to optimize quality through improving heat transfer rate. Foods in rigid polymer trays or flexible pouches heat more rapidly, owing to the thinner material and smaller cross-section of the container.

Much of the retort pouch development was conducted by the U.S. Army Natick Research and Development Center for use in the Meal Ready-to-Eat (MRE), having relatively light weight as compared to conventional metal containers. However, the thin thickness of the pouch and its flat shape allows fast heat penetration and contributes much on improvement of quality of foods as compared to conventional packaging materials. The retort pouch is a flexible, heat sealable container that is thermally processed like a can and used to produce shelf stable, commercially sterile food products. It is constructed of a 3-ply laminate composed of an outer layer of polyester film, a middle layer of aluminum foil, and an inner layer of polypropylene. The layers are bonded together with a special adhesive. The tri-laminate material provides seal integrity, toughness, puncture resistance, printability, and superior barrier properties for long shelf life. It also withstands the rigors of thermal processing up to 135°C.

Retort pouches are filled with wet foods sealed and then heat-treated in steam/hot water retort kettles to achieve commercial sterilization (for shelf-stable foods) or pasteurization (for refrigerated foods). Because processing time typically is faster in the pouch than in metal, glass, or rigid plastic containers, the product tends to end up with better quality and safety. Pouches also offer lower shipping and storage costs (pouch material is lighter than cans, and pouches take up less storage space than cans); easier, safer handling (no can openers or thawing time required); and reduced product waste and reduced volumes of disposed packaging waste material as compared to cans.

Some of the disadvantages include a lack of physical durability and slow production rates due to slow filling and sealing rate as compared to cans or glass jars. Furthermore, it needs an overpressure processing to protect the integrity of the packages during processing. Pouches are more easily punctured; they can overwrap for safe distribution.

Novel Thermal Food Processing Technologies

Microwave and Radio Frequency Heating

Microwave (MW; 300–300,000 MHz) and Radio Frequency (RF) waves (0.003–300 MHz) are a part of the electromagnetic spectrum. MW and RF energy generates heat in dielectric materials such as foods through dipole rotation and/or ionic polarization. MW ovens are now common household appliances. Popular industrial applications of MW heating in food processing operations include tempering meat or fish blocks and precooking bacon or meat patties, while RF heating is commonly used in finishing drying of freshly baked products. Such applications shorten processing times, reduce floor space, and improve product qualities compared to conventional methods.

Extensive research has been carried out over the past 50 years on MW and RF energy in pasteurization, sterilization, drying, rapid extraction, enhanced reaction kinetics, selective heating, disinfestations, etc., but with limited applications. Technological challenges remain and further research is needed for those applications. MW/RF sterilization applications demand more thorough and systematic studies as compared to other applications. These studies will have far reaching impacts to the food industry and research communities.

Several commercial 2450 MHz MW sterilization systems produce shelf-stable packaged foods in Europe (e.g., Tops Foods, Olen, Belgium) and Japan (Otsuka Chemical Co., Osaka), but these systems are designed with multi-mode MW cavities. Generally, MW/RF heating is a promising alternative to conventional methods of heat processing as it is regarded as a volumetric form of heating in which heat is generated within the product, which reduces cooking times and could potentially lead to a more uniform heating. Reduction in processing time and uniform heating results in getting high-quality product in terms of its nutrient content, desired flavor, texture, color, and taste.

Ohmic Heating

Ohmic heating (OH) is based on the passage of alternating electrical current through a food product that serves as an electrical resistance. Because of the current passing through the food sample and its resistance to the flowing current, relatively rapid heating occurs. OH has good energy efficiency since almost all of the electrical power supplied is transformed into heat. Many factors affect the heating rate of foods undergoing OH: electrical conductivities of fluid and particles, the product formulation, specific heat, particle size, shape, and concentration as well as particle orientation in the electric field.

As compared to conventional heating technologies, internal heat generation by OH eliminates the problems associated with the heat conduction in food materials and then prevents the problems associated with overcooking. Aseptic processing has been used commercially for long time for liquid foods, but for products containing particulates, the use of conventional heat-transfer techniques leads to overprocessing of the liquid phase to ensure that the center of a particulate is sterilized. This can result in destruction of flavors and nutrients, and mechanical damage to the particulate. However, OH-treated product is clearly superior in quality than those processed by conventional technologies. This is mainly due to its ability to heat materials rapidly and uniformly, leading to a less-aggressive thermal treatment. Hence, OH can be considered as a HTST aseptic process (Castro et al. 2004).

Novel Nonthermal Processing Technologies

High-Pressure Processing

High-pressure Processing (HPP) is an innovative technological concept that has a great potential for extending the shelf life of foods with minimal or no heat treatment. It is a process aimed at controlling deteriorative changes such as microbial and enzymatic activity without subjecting the product to drastic thermal processing and mass (drying) transfer techniques such that the original quality is retained.

The application of hydrostatic pressure to food results in the instantaneous and uniform transmission of the pressure throughout the product independent of the product volume. The treatment is unique in that the effects neither follow a concentration gradient nor change as a function of time. A significant advantage is the possibility of operation at low or ambient temperatures so that the food is essentially raw. Gelation, gelatinization, and texture modification can be achieved without the application of heat. Apparently, HPP is a physical treatment and is not expected to cause extensive chemical changes in food system. Once the desired pressure is reached, the pressure can be maintained without the need for further energy input. Liquid foods can be pumped to treatment pressures, held, and then decompressed aseptically for filling as with other aseptic processes.

HPP is a novel technique for processing of foods and has attracted considerable attention in recent years. It has been commercialized for a variety of acid and acidified food products. For low-acid foods, it has been used only as a temporary measure of extending the shelf life under refrigerated storage conditions. It has also been used for several other purposes, including control of some pathogens and viruses, for inducting functional changes, as well as improving nutritional and sensory quality of foods. HPP has been used mainly for refrigerated and high-acid foods. Pasteurization by HPP can be carried out at pressures in the range of 400–600 MPa at relatively moderate temperatures (20–50°C). Under these conditions, HPP can be effective in inactivating most vegetative pathogens and spoilage microorganisms, but the quality factors remain unaffected.

HPP for producing shelf-stable low-acid foods is still a topic of considerable controversy. It has the potential to produce better quality foods than possible from the use of processing novelties such as MW, RF, or OH techniques in combination with aseptic processing. This is because HPP allows the product temperature to increase very rapidly (due to adiabatic heating) from around 90–100°C to the sterilization zone (120–130°C; in about 2 minutes) and bring it back almost instantaneously by depressurization. The process can be formulated either as a pressure-assisted thermal processing. A better understanding of the inactivation kinetics of pathogens or their surrogates under pressure-assisted

thermal process conditions is the key for the success of the HPP and for regulatory approval.

The critical factors in the HPP include pressure, time to achieve treatment pressure, time at pressure, depressurization time, treatment temperature (including adiabatic heating), product initial temperature, vessel temperature distribution at pressure, product pH, product composition, product water activity, packaging material integrity, and concurrent processing aids. Although HP processing related research work has increased tremendously in the last decade, there is serious lack of information in this area to permit establishing a reliable process.

Pulsed Electric Field

Pulsed electric field (PEF) processing is a nonthermal method of food preservation that uses short bursts of electricity for microbial inactivation and causes minimal or no detrimental effect on food-quality attributes. PEF can be used for processing liquid and semi-liquid food products. PEF processing involves treating foods placed between electrodes by high-voltage pulses in the order of 20–80 kV (usually for a couple of microseconds). The applied high-voltage results in an electric field that causes microbial inactivation. A series of short, high-voltage pulses breaks the cell membranes of vegetative microorganisms in liquid media by expanding existing pores (electroporation) or creating new ones. The membranes of PEF-treated cells become permeable to small molecules; permeation causes swelling and eventual rupture of the cell membrane. The treatment is applied for less than one second, so there is little heating of the food, and it maintains its "fresh" appearance, shows little change in nutritional composition, and has a satisfactory shelf life (Castro et al. 1993, Kozempel et al. 1998). Since it preserves foods without using heat, foods treated this way retain their fresh aroma, taste, and appearance.

RETORT TYPES FOR COMMERCIAL APPLICATION

Retorts generally are either batch or continuous types. Their configuration may be either vertical or horizontal. Horizontal retorts are commonly preferred due to their ease of loading and unloading facilities as compared to vertical retorts.

Batch Retorts

Steam Heating Retort

In this type of retort (static or rotary), saturated steam is used as a heating medium. Latent heat is transferred from steam to the cans when saturated steam condensed at the surface of the cans. The saturated steam process is the oldest method of in-container sterilization. Since air is considered an insulating medium, saturating the retort vessel with steam is a requirement of the process. If air enters in the retort, it forms insulation layer of the surface of the can and prevents the condensation of steam and causes underprocessing of the product. It is inherent in the process that all air be evacuated from the retort by flooding the vessel with

steam and allowing the air to escape through vent valves. There is no overpressure during the sterilization phases of this process, since air is not permitted to enter the vessel at any time during any sterilization step. However, there may be air-overpressure applied during the cooling steps to prevent container deformation. This is because during cooling, the steam rapidly condenses in the retort and the food cools more slowly and pressure in the container remains high. When the food temperature becomes below $100°C$, overpressuring is stopped and the food is allowed to continuously cool up to $40°C$.

Water Heating Retort (Immersion and Spray Modes)

The water immersion process is the most widely accepted method of sterilizing product using an overpressure process. The water immersion process is similar to a saturated steam process in that the product is totally isolated from any influence of cooling air. The product is totally submerged in preheated water at preset temperature. But it is different from saturated steam in that air can be introduced into the vessel during sterilization. The water is preheated in different chamber with steam to desired temperature and pumped to retort chamber. Overpressure is provided by introducing air (or steam) on top of the water. In some instances, air is added to the steam (which then heats the air). The heated air agitates the water as it flows to the surface and serves to pressurize the process load. Because it is an overpressure process, the machine can handle most, if not all, of the fragile containers. For cooling, the water present in the retort passes through a heat exchanger, where it is gradually cooled by fresh water circulating in the service side.

The water spray process is also an overpressure process, like water immersion, except that the product is exposed to the influence of the overpressure air. In this retort, low amount of water is stored in the bottom of the retort and circulated by a pump with high flow rate and sprayed on containers. It is similar to the saturated steam process in that steam is the driving force for reaching the center of the load. But the water spray process is different from saturated steam in that air can be introduced into the vessel during sterilization. Overpressure is provided by introducing air (or steam) into the retort. To overcome the insulating effects of the air, the spray nozzles vaporize the steam and mix the steam with the air. The condensates are automatically evacuated by a drainer and can be returned to the boiler.

Steam-Air Heating Retort

The steam-air process is an overpressure process, like water immersion, except that the product is exposed to the influence of the overpressure air. Steam is directly injected inside the retort chamber and distributed and mixed uniformly with air with the help of a fan to prevent cold spots in the retort. It is a "ventless" process, resulting in significant energy savings. Furthermore, a precise control of the steam/air process results in a shortened cycle time for maximum production and consistent quality, and reduces the process time and optimal heat transfer characteristics, which allow foods to retain more of their natural qualities. The opening of the steam inlet valve is automatically

monitored, depending on the programmed temperature parameters. The pressure is also independently controlled from the temperature by injecting or venting compressed air.

Continuous Retorts

In continuous retort, filled and sealed containers are continuously moved from the atmospheric condition into steam-pressurized environment for desired degree of processing. In this process, cans enter a continuous retort and are instantaneously at the processing temperature; therefore, the process time is exactly the residence time of the cans within the retort.

Minimally Processed Foods

Michael O. Ngadi, Sammy S.S. Bajwa, and Joseph Alakali

Abstract: The widespread, strong and consistent demands for fresh-like and safe food products have been among the major factors driving innovative food processing technologies. The sometimes divergent requirements for food quality and safety have continued to challenge food scientists and engineers. Minimally processed foods are produced without or with mild heat treatment that result in safe products without quality degradation. To produce these products, nonthermal technologies are being introduced to replace or complement the well-established thermal processes. Techniques that combine different mild hurdles to restrict the growth of food spoiling microorganisms are also used. The hurdles are typically applied in a logical sequence to take advantage of possible synergistic interactions between them to enhance safety and quality of food products. The various techniques of minimal processing of foods are reviewed in this chapter along with the required packaging considerations that are needed for the processed products.

INTRODUCTION

The normal objective of food processing is to transform a product to ensure that it has adequate nutrient content, acceptable to consumers with respect to sensory and functional properties, and that it is microbiologically and chemically safe to consume. Thus, humans have traditionally embarked on series of activities and have taken advantage of various techniques, including various types of cooking, smoking, fermenting, sun drying, and salt preservation to transform food products. Nicolas Appert's introduction of canning and thermal processing revolutionized and set the stage for the modern food processing industry. Despite the huge market for canned and processed foods, there is strong and increasing demand for fresh and minimally processed health-centered foods. This demand for products with fresh-like characteristics has changed the traditional food processing mantra. New and lucrative markets are being developed for "fresh or fresher foods" that are "high" or "low" in certain target constituents (e.g., less salt, fat and sugar; and more in fiber and health-promoting chemicals). This rise in consumer health consciousness can be attributed to wide societal and scientific reawakening to the benefits of fresh products, including fruits and vegetables (Allende et al. 2006). Fresh fruits and vegetables are known to be of higher quality and rich in antioxidants, which are crucial in the fight against cancer (Flood et al. 2002). However, the recent and increasing incidences of food-borne pathogens in food products have heightened the alert for increased food safety. Although Canada has one of the best

food safety systems in the world, outbreaks of illness that are linked to consumption of fresh fruits and vegetables have been reported. The Public Health Agency of Canada, Health Canada, and the Canadian Food Inspection Agency have been coordinating to identify gaps, develop and enforce solutions to improve the Government's response to outbreaks, and to ensure Canadians are provided with the highest levels of food safety protection.

Food quality and safety are not necessarily complementary. In fact, they are opposing in some cases. The balance and optimization of the two parameters has been a major challenge in food processing. The use of intense and broad-spectrum technologies such as thermal treatment for microbial inactivation and shelf life extension are known to be effective but unfortunately result in accelerated degradation of sensory, nutritive, and functional quality of food products. There is also the aspect of excessive energy use with some of the food processing technologies. More recent technological advancements have allowed the application of mild processing of food with the promise of safe products without the downside of quality degradation. These technologies are termed as minimal processing technologies, and food products obtained by their applications are referred to as minimally processed foods. Thus, minimally processed products have not undergone very extensive transformation, particularly thermal processing as compared to conventional foods. The aim of each minimal processing technique is to minimize the rate of deterioration within the food matrix.

OVERVIEW OF THERMAL PROCESSING TECHNIQUES

Thermal processing involves the application of adequate heat to inactivate undesired spoilage microorganisms, degrading enzymes, and antinutrients, and prepare the food product to be consumed. It is robust and widely used in processing and preserving foods. Sufficient heat destroys microorganisms and food enzymes but also impacts both desirable (textural changes, protein coagulation, and release of aroma) and undesirable changes (nutrient loss, loss of freshness) in the food. Thus, in practice, designing appropriate thermal process typically involves consideration of time–temperature combinations that are required to inactivate the most heat-resistant pathogens and spoilage organisms in a given food matrix. There is often the need to evaluate heat penetration characteristics in a given food product, including can or container in order to evaluate temperature distributions. The choice of process depends on the minimum possible heat treatment that should guarantee freedom from pathogens and toxins and give the desired quality and storage life.

HIGH TEMPERATURE SHORT TIME PROCESS

The mechanism of heat destruction of microorganisms has been attributed to thermally induced changes in the chemical structure of proteins in the cells. The phenomenon can be described by a first-order reaction equation.

$$\frac{dN}{dt} = -k_{o}Ne^{\left(-\frac{E}{RT}\right)} \tag{1}$$

where N is concentration, t is process time, k_{o} is the activation factor, E is activation energy, and T is absolute temperature. Along with the microbial inactivation, other chemical reactions that occur during thermal processing lead to degradation of various quality attributes (sensory, vitamin C, thiamine, flavor, etc.). These degradation reactions can also be described using kinetic equations similar to Equation 1 with their relevant activation factors and activation energies. Several studies have confirmed that at high temperatures, the destruction rate of pathogenic bacteria accelerated more rapidly than the degradation rate of nutrients (Holdsworth 1985). The z-value (defined as change in the death or degradation rate based on temperature, i.e., the change in temperature required for tenfold change in microbial or chemical resistance) is typically around 10°C for microbial death, whereas the value for chemical degradation is around 30°C. Thus, the interaction between safety and quality can be examined by considering microbial death kinetics and chemical degradation kinetics.

High temperature short time (HTST) process takes advantage of the differences in the microbial inactivation and quality degradation kinetics to improve retention of nutrients (higher quality) while ensuring adequate microbial inactivation. Temperature–time combinations used for HTST may range from about 72°C for 15 seconds for pasteurization of milk to much higher temperatures for shorter times. It is typically applied at about 132–143°C for different times depending on the required F_{o} values (the amount of time a food is maintained at the reference temperature of 121.11°C; used as a benchmark and indicating the severity of a process) to sterilize low-acid foods and beverages. The use of temperatures beyond 138°C is usually referred to as ultra high temperature (UHT) processing. A major limitation associated with HTST lies in its application to products that are highly viscous, solid, or that contain solid particles. Safety considerations require that sufficient heat is applied to sterilize the fastest moving (which is really the slowest heating) particle in the system. This implies that other slower moving particles are overprocessed, since they receive the high temperature but not the short time, resulting in degraded quality of the product. There are also limitations of heat transfer rate in solids, which may lead to surface heating and reduced quality. These limitations create a need for other technologies for effective delivery of energy to the product to enhance both safety and quality.

ASEPTIC PROCESSING

Aseptic processing is an answer to the limitations of HTST. In this technique, processed food products and package are brought together aseptically (i.e., in a sterile environment). Liquid food product is initially sterilized by HTST or UHT and then heat is transferred to the solid particulate components as they are transported by the liquid and filled into presterilized containers. This revolutionary packaging system first appeared in US supermarkets in the 1970s (Fellows 1988, Holdsworth 1992, Welch and Mitchell 2000). In 1989, the Institute of Food Technologist selected aseptic packaging as "the most significant food science innovation in the past fifty years." An aseptic process for a low-acid product containing particulates (potato soup) was filed

with the Food and Drug Administration in 1997 by Tetra Pak, following two workshops conducted in 1995 and 1996 by Center for Advanced Processing and Packaging Studies (multi-University partnership of The Ohio State University, North Carolina State University, and University of California-Davis) and the National Center for Food Safety and Technology.

Aseptically processed products have shelf life of 1–2 years and they have superior sensory and nutritional characteristics compared to conventional thermally processed products. Some of the difficulties associated with the techniques include variation of residence time of particulates in different parts of the processing equipment, control of heat transfer rate between heated liquid and solid particulates, fouling in heat exchangers, potential survival of enzymes, and potential damage to solids by pumping.

Sous-Vide Processing

Sous vide is a French word, which essentially means under vacuum. Chef Georges Pralus is credited with using sous-vide cooking for the first time to reduce shrinkage on a foie gras terrine by cooking in a laminated plastic film sachets in France in 1967. In this technique, ingredients or the raw food materials are put in a plastic pouch, vacuum sealed and pasteurized at varying time–temperature combinations (usually below 100°C and time longer than traditional cooking). The products can be regarded as minimally processed since they are typically cooked at lower temperatures. After being cooked, the food is cooled to temperatures in the range of 1–8°C. Sous vide is increasingly being used to process convenience foods (ready-to-eat meals) as it is reputed to produce superior quality product because of the mild heat processing and the absence of oxygen in the pack (Creed 2001). Pasteurized sous-vide pouches when held below 3.3°C remain safe and palatable up to 3–4 weeks (Armstrong and McIlveen 2000, Nyati 2000, Rybka-Rodgers 2001, González-Fandos et al. 2005, Peck and Stringer 2005). Sous-vide processed products retain fresh-like textures and superior flavors. They also tend to show higher mineral, vitamin, and color retention. However, inappropriate heating, refrigeration, and storage temperatures can be the breeding ground for *Clostridium botulinum* and more specifically the type A, B, and E spores, which can produce toxins dangerous for human health. After *Clostridium botulinum*, *Listeria* is the most heat-resistant non-spore forming pathogen that has the ability to grow at refrigerator temperatures. Therefore, there is greater risk for food poisoning, and it is important to achieve 6D reduction (Rybka-Rodgers 2001). It is vital to use the sous-vide techniques within systems that minimizes contamination. At industrial level, there is need to implement HACCP practices to get high-quality and microbiologically safe minimally processed food.

Electrical Heating of Foods

In electrical heating, electromagnetic energy is applied to increase the temperature of a product in such a way that the entire volume and not just a part of the product is heated rapidly in order to minimize quality losses. The technique was developed to address the limitation of conventional surface conduction-based methods. As a result of the rapid heating, quality changes in electrical processed foods are generally better and are more controlled compared to HTST processing. Electric heating of different foods can be achieved by using different methods, including ohmic heating, microwave, radio frequency (RF), and infrared heating.

Ohmic Heating

Ohmic heating involves passing electric currents (primarily alternating currents) through a food product for the purpose of heating it. The process is also sometimes called Joule heating, electrical resistance heating, direct electroheating, and electroconductive heating. Heat is generated internally in the product as a result of its electrical resistivity. The electrical resistance of the food determines the extent of current or voltage and the relative amount of heat generated. It is a promising method of food processing as the food heats volumetrically and provides the potential to reduce overprocessing problems associated with typical inside–outside heating pattern of conventional heat transfer (Lima 2007, Wang et al. 2007b). The process is efficient for foods with large particulates, which are not easy to process by conventional thermal processing techniques. Rapid heat rates greater than 1°C/s can be obtained along with considerable energy saving with better control of process parameters (temperature and time).

Ohmic heating systems typically use electrodes contacting the food. Applications of the technology include evaporation, blanching, dehydration, and extraction. Zhong and Lima (2003) studied the effect of ohmic heating on drying rate of sweet potatoes. The authors reported that ohmic heating of potato increased the vacuum drying rate and 24% drying time was saved, which is crucial in controlling economics of the process. The technique is being used in the United States and Japan for processing strawberries and different fruits to be used in yogurt preparation (Sastry and Barach 2000, Castro et al. 2003). Red apple, golden apple, peach, pear, pineapple, and strawberry have been heated ohmically in the temperature range of up to 25–140°C (Sarang et al. 2008). It has been reported that the application of electric current has no impact on the rheological, color, and chemical content of ohmically treated liquid juice (Yildiz et al. 2009). Quality of carrot pieces that had received varied thermal treatments, such as blanching at low and high temperatures, were tested for qualitative changes when three different heating methods, namely conventional, microwave, and ohmic heating, were applied. It was observed that time/temperature of thermal pretreatment rather than method of heating influenced quality of products (Lemmens et al. 2009).

Dielectric Heating

RF heating and microwave (MW) heating are based on the use of electromagnetic energy to quickly heat foods. When poor conducting dielectric food products are brought into a rapidly altering electrical field, the H^+ and OH^- components of water molecule separate to form an electric dipole and orient themselves in the direction of the applied varying electric field. Thus,

there is dipole rotation and ionic polarization resulting in volumetric heat generation in the food (Metaxas and Meredith 1993). The extent of energy absorption by the food sample depends on its dielectric loss factor. The higher the loss factor, the more energy can be absorbed in the material. Chemical composition, including water and salt, and process temperature are among the factors that determine the materials loss factor. Although RF and MW heating are forms of dielectric heating, they are distinct from technological point of view. Both systems are operated at specific bands, namely frequencies between 0.003 and 300 MHz for RF and between 300 and 300,000 MHz for microwaves (Ramaswamy and Tung 2008). RF systems have longer wavelengths compared to MW systems. Thus, the penetration depth is typically smaller for MW heating. In general, the efficiency of power utilization is far lower in a RF generator than a microwave unit, although the initial capital cost per KW of power output may be higher. Selection of RF or MW heating usually depends on product physical properties and required process conditions for a particular application. For large products where greater penetration depth is required and control of uniformity of heating is not a major issue, RF offers a good solution. However, microwave systems are preferred where uniformity of drying and moisture control is essential.

The earlier applications of RF heating in fruit and vegetable processing was carried out for vegetable dehydration and quality assessment of juice from orange, peach, and quince (Kinn 1947, Moyer and Stotz 1947, Demeczky 1974). Nelson and Trabesli (2009) explained how dielectric properties of fruits affect their heating characteristics. RF-based treatments have been widely used in postharvest operations (Ikediala et al. 2000, Wang et al. 2006, 2009a). Wang et al. (2006) proposed the use of radio frequencies at various levels to control insect infestation without compromising quality aspects. Sosa-Morales et al. (2009) noted that RF and MW treatments can be highly efficient in reducing the heating time required for pest control, as compared to conventional thermal treatments. Water-assisted RF heating treatment was used to control the infestation of apples by codling moth, and it was reported to be an efficient technique, which also sustained the fruit's quality (Wang et al. 2005, Wang et al. 2006). Further, RF electric field has been used in deactivating *E. coli* bacteria in apple and orange juice (Geveke et al. 2007). Despite the clear advantages of RF heating, the problem of uneven heating imposes a big hurdle in its wide acceptance. There is ongoing effort to mitigate some of these problems using computer modeling (Birla et al. 2008). New and advanced RF systems are being developed to improve heating applications.

MW-based processing systems are more widely used for either domestic or commercial food preparations. There has been considerable advance in the design, power, and cost features of these systems since their introduction for small scale heating applications. The reliability of MW-assisted treatment of fruits and vegetables has been rated high over the conventional heating methods (Vadivambal and Jayas 2007). MW-assisted drying has proved to be an excellent technique for processing the raw fruits and vegetables. The technique was used to study drying behavior of various fruits like apples, mangoes, and carrots (Wang and Xi 2005, Orsat et al. 2006, Zhang et al. 2006, Vadivambal and Jayas 2007). Various fruits and vegetables have been reviewed to assess the effect of varying microwave conditions on banana slice, cranberries, and carrots (Drouzas and Schubert 1996, Yongsawatddigul and Gunasekaran 1996a, 1996b, Tein et al. 1998). Also, there has been use of vacuum for assisting microwave drying to remove the moisture. Chou and Chua (2001) reported that it was necessary to combine MW drying with vacuum in order to improve drying performance. Many other authors (Table 39.1) have combined MW with other heating techniques in order to reduce process energy and produce high-quality products.

There are some indication of nonthermal and enhanced thermal effects of microwave processing (Ramaswamy et al. 2002, Datta and Anantheswaran 2004). However, it is generally

Note: The objectives of researches shown may differ.

believed that the kinetics of microbial inactivation in microwave processing is essentially same as the inactivation kinetics of conventional thermal processing for the same heating rate. Recent technological advancement, including development of new chemical marker system for process monitoring and identification of cold spots, techniques for achieving temperature uniformity, computer modeling, and microbial inactivation validation, has led to US FDA approval of microwave sterilization in 2009. This clears the path for commercialization of the process. There is no report of industrial application of RF sterilization (Ramaswamy and Tang 2008). There is a need to speed up research and development efforts to enhance MF- and RF-based industrial sterilization processes.

NONTHERMAL PROCESSING TECHNOLOGIES

Traditional thermal processing technologies are well established and proven to inactivate microorganism and prolong shelf life in foods. However, some of the challenges associated with maintaining product quality and freshness have been discussed in the preceding sections. Nonthermal technologies that inactivate microorganisms by means other than heat are being introduced to mitigate some of the shortcomings of traditional processes. These technologies include high pressure, pulsed electric fields, irradiation and pulsed ultraviolet (UV) light, etc.

HIGH-PRESSURE PROCESSING

High-pressure processing (HPP) of foods is the application of ultra high pressure (100–1000 MPa) on foods for short duration, which may range from few seconds to minutes. The most important aspect of HPP lies in its effectiveness in microbial control in food products. HPP has shown its potential in keeping food fresh for long time without the use of preservatives, in inactivating food-spoiling microbes, and most importantly in maintaining minimally processed fresh-like texture. The technique was initially commercialized in Japan in 1990s, but, historically, the United States was the first country to use the HPP technology for preserving products like juice, some fruits, milk, etc. The monetary constraints and lack of expertise in high-pressure equipment and package manufacturing emerged as a roadblock until Japan reinitiated use of this technology in 1980s. There have been an increasing number of HPP systems installed throughout the world. In 2008, there were four systems (71 overall) systems in North America (Campus 2010). A wide range of products including juices, fruits and fruit related products, seafood, and meat products have been successfully processed using the technology.

HPP operations can be conducted in three modes, namely batch, semi-continuous, and continuous modes. Semi-continuous or continuous modes typically apply to pumpable products, in which case aseptic packaging is required. Products can be processed in-package in batch mode. A flexible package like a retort pouch or plastic bottle is introduced in a high-pressure chamber, and pressure is transmitted to the food via its package by the use of a hydraulic liquid. Water is preferred as the hydraulic liquid because of operational ease and high compatibility with the food components. HPP packages must be airtight and capable of allowing about 19% decrease in volume without losing seal integrity. Juliano et al. (2010) have provided a good review on packaging concepts for HPP. Since pressure is transmitted uniformly in all directions, the texture of processed product, as well as nutritional and sensory attributes of the food product, is preserved in HPP processing (Fernandez et al. 2001).

Typical HPP system comprises of four components, namely pressure vessel, pressure generating device, pressure and temperature control, and material handling units (Mertens 1995). Pressure vessels are designed carefully to meet very strict safety and operational standards of the American Society of Mechanical Engineers (ASME) boiler and pressure vessel codes. To withstand the high pressures used in HPP, prestressed multilayer or wire-wound vessels are used. High pressure can be generated either by direct or indirect compression or simply by heating the pressure fluid. In the more widely used indirect compression, water (or other pressure transmitting fluid) is pumped into a closed high-pressure vessel until the desired pressure is achieved (Mertens 1995). Technological developments on design of pressure vessels and intensifiers are the major driving advances in the HPP technology. Early HPP systems were operated with vertical vessels. Recently in 2000, NC Hyperbaric, one of the leading HP manufactures introduced the first horizontal HPP vessel. Information from the company suggests that installation and product handling in a horizontal system is reported to be much easier and less expensive than the vertical system (www.nchyperbaric.com). In particular, loading and unloading motions in the horizontal machines are made at the waist level and can be more easily done either manually or automatically than in the vertical systems, which are typically several meters high.

High pressure inactivates microorganisms by increasing the permeability of the cell membrane, causing loss of intracellular fluids, thereby inhibiting biochemical reactions within the cell and hampering cell growth (Cheftel 1995, Ananta et al. 2001). On application of high pressure, the acyl chains get tightly packed with the phospholipid bilayer of membranes, and it undergoes transition from liquid crystalline to gel phase, hence modifying the internal microbial resistance. Variation in time–pressure conditions affects the cytokinetic and mitotic activity of the cell (Lopes et al. 2010). Presence of at least 40% free moisture content is important for effective microbe destruction (Earnshaw 1996). Gill and Ramaswamy (2008) used a pressure of about 600 MPa with holding time of about 3 minutes on two RTE meats (Hungarian salami and All beef salami) inoculated with food-borne pathogen *E. coli* O157. It was observed that there was reduction in *E. coli* count in both samples. However, when samples were enriched with nutrient medium to recover *E. coli*, there was increase in the *E. coli* count of Hungarian salami, whereas stagnant *E. coli* count was found in all beef salami that was conditioned in regulated pH and water activity. Bacterial spores are of small size, low in moisture content, and impermeable to water, which makes them highly resistive to intense pressure conditions. They are considered as potential danger in postprocessing storage, as they may germinate and cause food toxification. Spores can tolerate pressure up to

1000 MPa (Cheftel 1995). There is a long list of spore-forming bacterium that spoils food such as milk, cheese, meat, juices, etc. The spores of *Bacillus* and *Clostridium* species have been cited as the common reason for food-borne diseases (Shapiro et al. 1998, Salkinoja-Salonen et al. 1999, Borge et al. 2001, Brown 2000). An elaborate review of studies on spore inactivation has been given by Black et al. (2007). Although HPP has shown great potential as a reliable processing technique, very high pressures may result in poor quality. Thus, in some cases, combination of HPP with other factors (such as temperature, pH, water activity, etc.) may be beneficial. There is increasing interest in the high pressure, high temperature or Pressure-Assisted Thermal Sterilization or Pressure-Assisted Thermal Processing (PATP) for development of shelf-stable low-acid food products (Barbosa-Canovas and Juliano 2007, Zhu et al. 2008).

PULSE ELECTRIC FIELD PROCESSING

Pulse electric field (PEF) processing of foods is growing in importance as a technique for producing microbiologically safe, nutritious, fresh-like, and high-quality products (Mittal 2009). There are also economic and energy-saving advantages associated with the technology. It has been used for processing liquid food products like fruit juices, alcoholic beverages, soups, liquid eggs, and milk. It can be used in continuous for pumpable fluids or in batch modes for both liquids and solids.

PEF processing is based on the principle of application of electric field (20–80 kV/cm) on a food product contained between two electrodes in short pulses (1–100 μs). Microbial cells present in the food are inactivated and drastically reduced in count. Electric breakdown of cells and electroporation are the two mechanisms of microbial destruction during PEF (Zimmermann 1986, Harrison et al. 1997, Barbosa-Canovas and Sepulveda 2005). In electric breakdown mechanism, application of external electric field causes development of electrical potential difference across cell membrane, also called as transmembrane potential. When the transmembrane potential is higher than the natural potential of the cell (nearly 1 V), pores are formed, reducing the thickness of cell membrane. With higher potential, the cell membrane is eventually disrupted permanently, leading to cell destruction. With respect to the electroporation mechanism, lipid bilayers and proteins are destabilized, increasing membrane permeability and number of pores. The pores cause the cell membrane to rupture, cytoplasmic material oozes out, and finally cell dies (Vega-Mercado et al. 1997). Effective application of PEF depends on the type of pulse (monopolar and bipolar) and waveform (sinusoidal, square, or exponentially decaying) used (Ho and Mittal 2000, Ngadi and Bazhal 2004).

Earlier application of PEF in food processing in North America focused on pasteurization of liquid or semi-liquid products. Some of the foods that have been processed using the technology include milk (Evrendilek and Zhang 2005), apple juice (Vega-Mercado et al. 1997, Sanchez-Vega et al. 2009), orange juice (Rivas et al. 2006), liquid egg (Martin-Belloso et al. 1997, Amiali et al. 2006, Amiali et al. 2007), and egg yolk (Bazhal et al. 2006). These studies and others showed that PEF can be used to successfully inactivate pathogenic and food spoilage microorganisms as well as selected enzymes, resulting in better retention of flavors, nutrients, and fresher taste compared to heat-pasteurized products. Mosqueda-Melgar et al. (2007) reported efficacy of PEF in decreasing *Salmonella* spp., *E. coli* and *L. monocytogenes* in melon and watermelon fruit juices. A reduction in the bacterial yeast and mould count in naturally contaminated orange juice was observed. The color, aroma, and flavor features were better than as in conventional HTST treatments. PEF was also effective in inactivating yeast (*Saccharomyces cerevisae*) and bacteria (*Kloeckera apiculata, Lactobacillus plantarum, Lactobacillus hilgardii, and Gluconobacter oxydans*) present in grape juice (Marsellés-Fontanet et al. 2009). Many factors influence effectiveness of PEF processing. These include process factors (electric field strength, number of pulses, treatment time, treatment temperature, pulse shape, pulse width, pulse polarization, frequency, specific energy, treatment chamber design, etc.), microbial factors (cell concentration, microorganism resistance to environmental factors, type and species of the microorganism, as well as growth conditions such as medium composition, temperature and oxygen concentration and other stress conditions), and product parameters (product composition, presence or absence of particles, sugars, salt and thickeners, conductivity, ionic strength, pH, water activity, etc.). Optimal application of PEF often involves appropriate control of these factors. There has been effort to develop mathematical models that will describe the complex mechanism of microbial inactivation using PEF. Research is still ongoing to discover suitable models. However, typical inactivation characteristics tend to follow the sigmoidal shape and may be described using kinetic-based or probability-based models. Table 39.2 indicates how different parameters might influence microbial inactivation using PEF.

Although the influence of PEF on microbial inactivation is well established, there are varying reports on its effect on quality of processed liquids. There was high retention of lycopene and vitamin C in water melon juice (Oms-Oliu et al. 2009), higher vitamin A in orange–carrot juices (Torregrosa et al. 2006), higher phenolic content and antioxidant capacity in strawberry juice (Odriozola-Serrano et al. 2008), and no change in phenolic content of tomato juice (Odriozola-Serrano et al. 2009) with PEF processing. A new orange juice-milk beverage was developed by insertion of bioactive components (*n*-3 fatty acids and oleic acid) as an alternative to soft drinks. The effect of PEF at two levels, namely 35 and 40 kV/cm, was used to study effects on physicochemical properties, pH, degree Brix, and peroxide index. The study concluded that there was no significance effect of PEF treatment on saturated and unsaturated fatty acid contents, with no detection of peroxide and tolerable levels of furfurals (Zulueta et al. 2007).

PEF treatment may influence physical and chemical properties of products. The nature and extent of PEF influence on quality changes are still being actively discussed. Ngadi et al. (2010) provided an excellent review of quality aspects of PEF processing. Barsotti et al. (2002) indicated that PEF treatment of model emulsions and liquid dairy cream may result in dispersal of oil droplets and dissociation of fat globule aggregates. Qin et al. (1995) reported no apparent change in the physical and chemical attributes of PEF-processed milk. PEF

treatment of various liquid foods, including apple juice, orange juice, and milk, has not shown any significant physicochemical changes. PEF-processed yogurt-based drink retained its physical and chemical characteristics (Evrendilek et al. 2004). There was a slight decrease in vitamin C content in PEF-treated orange juice compared to heat-treated orange juice (Zhang et al. 1997). In a comparative study of orange juice pasteurized by ultra-high temperature (processing at 110°C, 120°C, and 130°C for 2 and 4 s) and PEF (20 and 25 kV/cm for 2 ms), Gallardo-Reyes et al. (2008) concluded that although there was no difference in pH and soluble solids obtained with both treatments and freshly squeezed control samples, the color of PEF-treated sample was closer to the control. PEF inactivates various types of enzymes. A reduction of about 95% in the residual activity of polyphenol oxidase (PPO) in apple juice was observed when treated with PEF. Decreased pectin methylesterase (PME) and PPO activity and nonenzymatic browning were observed in the carrot juice (Luo et al. 2008). When treated with PEF, strawberry, tomato, and water melon juice noticed a decreased level of nonenzymatic browning (Aguilo-Aguayo et al. 2009a, 2009b). The activity of lipoxygenase and β-glucosidase in strawberry juice was reduced effectively (Aguilo-Aguayo et al. 2008). There are indications that as a result of its influence on enzymes and bioactive compounds, PEF may affect quality of cheese produced using PEF-processed milk. Electric field intensity (E) and treatment temperature significantly affected rennet

coagulation properties of milk in terms of curd firmness (Yu et al. 2010). The result implied that treating milk with PEF and mild temperature impact less changes in terms of milk coagulation properties compared to conventional heat pasteurization. This result is consistent with the finding of Dunn (1996), who studied the PEF-treated raw milk and concluded that no significant physicochemical changes were observed.

Although the interest is increasing rapidly, there is much less information on application of PEF on solid food materials. Bazhal et al. (2003) applied 300 μs pulses of 1 kV/cm at the rate of 1 Hz on apple tissues and studied the resulting structural and morphological changes. The authors reported an increase of porosity from 63% to 69.4% after PEF electroplasmolysis. The sizes of the induced pores were smaller compared to the pores of untreated samples and were comparable with the tissue cell-wall thickness. When PEF-treated apple slices were compressed, it was observed that there was a relationship between mechanical failure stress and degree of electroplasmolysis as shown in Figure 39.1. Influences of PEF on physical and textural properties of food materials have been reported (Rastogi et al. 1999, Angersbach et al. 2000, Gadmundsson and Hafsteinsson 2001, Taiwo et al. 2001, Gachovska et al. 2009, Grimi et al. 2009). Several other authors have exploited this phenomenon in using PEF to enhance extraction of juice from different food materials (Bazhal and Vorobiev 2000, Eshtiaghi and Knorr 2002, Gachovska et al. 2006, Gachovska et al. 2008, Gachovska et al. 2010, Hou et al. 2010, Loginova et al. 2010). The various studies indicate improved pressing efficiency, faster extraction processes, and improvement in drying processes as advantages of PEF-enhanced

Figure 39.1. Typical stress–strain curves from the compression test on apple samples treated by electric field pulses (field strength, $E =$ 1 kV/cm; treatment time = 300 μs; frequency = 1 Hz). Control sample has no treatment ($n = 0$) (Bazhal et al. 2004).

processes. Despite the enormous progress that has been made on PEF processing of food, some of the challenges of the technology include difficulty in comparing different systems and process parameters. Different equipment and treatment chambers may present different treatment conditions. There is need to standardize various parameters and systems in order to facilitate effective evaluation of various processes reported by various authors.

LOW-DOSE IRRADIATION

Ionizing radiations have been used to control spoilage microorganisms and extend food shelf life. As it involves no heating, the food retains most of its organoleptic features. The technique involves application of precisely controlled ionizing radiation to either bulk or packaged product for a preestablished duration in order to destroy microorganisms, insects, or other pests; minimize postharvest losses; decrease or inhibit sprouting; or other specific purposes. The form of ionizing radiations used in food processing includes gamma rays from radioisotopic sources such as Cobalt-60 or Cesium-137, high-energy electrons from electron beam devices, and X-rays from electron beam accelerators (Patterson and Loaharanu 2000). The use of gamma rays or X-rays of energies no greater than 5 MeV is generally recommended for food processing, whereas for accelerated electrons, energy levels below 10 MeV are suitable (Wilkinson and Gould 1998). The mechanism of microbial inactivation by ionizing radiations has been ascribed to direct interaction of the radiation with cell components and food molecules or indirect action from radiolytic products such as water radicals H+, OH−, and e$_{aq}$ (Wilkinson and Gould 1998, Morris et al. 2007). It primarily targets the cell's chromosomal DNA and exerts a secondary effect on the cytoplasmic membrane, either of which can result in microbial inhibition or inactivation. Energy from the radiation sources may be sufficient to dislodge electrons from food molecules, converting them to electrically charged particles or ions. However, the ionizations are too low to induce radioactivity in food products. To irradiate the food, it is important to use the radiations that can reach the core of the irradiated food in order to achieve uniform treatment. Gamma rays have high penetrating power and thus can be used to treat foods in large packages. The energy decreases exponentially with depth of the absorbing product. However, accelerated electron beams continuously lose energy in a series of interactions with orbital electrons in the absorbing medium. Their penetration depth is low such that 10 MeV electrons may only penetrate about 4 cm (Wilkinson and Gould 1998).

Microorganisms, enzymes, insects, and vegetable sprouting have different degrees of sensitivity to radiation. Required irradiation doses for a specific goal depend on the rays (type, quantity, and radiation time) and the irradiated environment (absorption capacity, physical, chemical and biological modifications, and secondary reactions). Irradiation dose is measured in grays (Gy), defined as the absorption of 1 J of ionizing radiation by 1 kg of matter (i.e., 1 Gy = 1 J/kg). High-radiation dose in the range of 10–74 kGy is usually applied for microbial sterilization (Morris et al. 2007). Milder doses less than 10 kGy
have been applied for pasteurization applications (Patterson and Loaharanu 2000). Although high irradiation doses have intense and effective microbial inactivation action, they are not preferred since they also destroy organoleptic features of the food material. Thus, low doses of radiation that are severe enough to reduce microbial populations and maintain sensorial and nutritional quality of foods are generally applied. FDA regulations specify the maximum radiation dose for control of food-borne pathogens in fresh or frozen, uncooked poultry products (3 kGy); refrigerated, uncooked meat products (4.5 kGy); and frozen, uncooked meat products (7 kGy) (FDA 2005, Komolprasert 2007). Low dose (1 kGy maximum) is imposed for control of growth and maturation inhibition in fresh foods. However, much higher dose of 30 kGy is imposed for microbial disinfection of dry or dehydrated spices.

Many studies have demonstrated that low-dose radiation is useful in improving microbiological safety of fresh-cut fruits and vegetables without significant change in appearance, texture, flavor, or nutrition quality (Kim et al. 2006, Niemira and Fan 2009). Gamma radiation of broccoli, cabbage, tomatoes, and mung bean sprouts at the dose of 1 kGy resulted in more than 4 log reduction in *Listeria monocytogenes* without significant changes in appearance, color, taste, and overall acceptability (Bari et al. 2005). Usage of low energy X-ray irradiation (1 kGy surface dose) on lettuce caused 5 D reduction in *E. coli* O157:H7 (Jeong et al. 2010). Reduction in the *E. coli* O157:H7 count without any effect on quality of spinach leaves was noticed when gamma irradiation (doses of 0.3–1 kGy) was used (Gomes et al. 2008). Along with the effect on microorganism, radiation also denatures enzymes in foods. Latorre et al. (2010) reported that when red beets were treated with 1–2 kGy gamma radiation, peroxidase (POX) activity increased significantly with the increasing radiation dose, whereas PPO activity increased only for a radiation dose of 2 kGy. The trend was attributed to the higher stiffness and to the rise in tissue elasticity after irradiation. As a result, color pigments such as betacyanin and betaxanthin did not change after 1 kGy radiation but decreased sharply at 2 kGy. A detailed review on the use of irradiation in the fruits and vegetables has been given by Arvanitoyannis et al. (2009).

There are challenges associated with producing and marketing irradiated food products. Although it is well established that food products processed using appropriate low dose of radiation is safe to consume, there continues to be some widespread hesitation by consumers. There is a strong opposition in the European Union to irradiated foods, but as food safety takes center stage internationally and people prioritize food safety, these attitudes may shift. In the United States, a large number of irradiated food products are available and without any significant opposition from consumers. There are strict regulations limiting the marketing of irradiated products in the United States. The Federal Food, Drug and Cosmetic Act deems a food product to be adulterated if it has been intentionally irradiated (unless the irradiation is carried out in compliance with an applicable regulation under the prescribed conditions of use specified in the regulation). Irradiated products are required to be adequately labeled. Further, since most foods are generally prepackaged in their final form before irradiation, there are serious constrains

on the type of packaging materials that can be used. Komolprasert (2007) discussed some of the constraints of irradiation on packaging materials. To ensure that components of the packaging materials that have been irradiated at a given level do not migrate into the food, the regulation stipulates that the use of packaging materials for irradiated food is considered a new use and is subject to premarket safety evaluation and approval. In general, development of new methods of irradiation detection and chemical analysis of trace elements in foods could expedite introduction of safe and quality irradiated products and enhance consumer confidence in accepting the products.

ULTRASOUND

Ultrasound processing is the application of high-intensity sound waves (20–100 kHz) on foods. The technology can be used mainly in two ways: as a diagnostic tool for nondestructive quality evaluation and as energy for processing (Mason et al. 2005). In the past, ultrasound has been used in quality assessment of agricultural produce (preharvest and postharvest) but is now increasingly being applied in processing. Ultrasound can be applied for various operations such as cell disintegration, extraction (phenolic compounds, pigments, lipids, proteins), mixing, acceleration of enzyme activity and microbial fermentation, emulsification, fruit juice processing, and many other uses. Further, ultrasound has also been used for enzyme inactivation and microbial reduction in food. The effectiveness of ultrasound in its antimicrobial action is based on controlling critical factors such as frequency and intensity of wave and time of exposure. Actual application depends on the type of microorganism, temperature, and the nature of the food. In fluid systems, ultrasound induces rapid appearance, growth, and collapse of bubbles or cavitations, leading to considerable agitation, localized "hot spots," and increased bulk transport within the mass (Mulet et al. 2003). In solids, ultrasound produces series of rapid compression and expansions of the material comparable to repeated squeezing and releasing of a sponge, which enhances mass transfer and creates microchannels for fluid movement (Floros and Liang 1994). Thus, when applied to solid–fluid systems, both internal and external resistances to mass transfer between the solid and liquid phases are affected. The interaction of ultrasound in solid–fluid interfaces can produce a microagitation in the immediate vicinity of the solid surface, resulting in reduction of diffusion boundary layer thickness (Mulet et al. 2010). It was reported that the extractive value of herbs such as for fennel, hops, marigold, and mint increased by 34%, 18%, 2%, and 3%, respectively, in water, whereas in ethanol, there was an increase of 34%, 12%, 3%, and 7%, respectively, when ultrasound extraction was applied when compared to conventional methods (Vinatoru 2001). Different solvents may present varying effect on extraction effectiveness of ultrasound. For extraction of carnosic acid from rosemary, ultrasound improved the relative performance of ethanol such that it was comparable to butanone and ethyl acetate alone. Thus, ultrasonication may reduce the dependence on harsh solvents and enable use of environmentally benign solvents (Albu et al. 2004). Knorr et al. (2004) and Vilkhu et al. (2008) provided good review of applications of ultrasound in the food industry.

More recent reviews on the technology are Soria and Villamiel (2010) and Chemat et al. (2010).

Different bacteria exhibit different sensitivities to ultrasonic treatment in different media (Wang et al. 2010). Early applications of ultrasound showed relatively low microbial inactivations. However, there has been considerable progress in equipment development that has resulted in increased inactivations but typically below 5 logs. Application of ultrasound alone is not very effective for microbial inactivation in commercial processing, but the technique can be effective when used in combination with other treatments (Raso et al. 1998). Thus, three different techniques, namely thermosonication, manosonication, and manothermosonication have been promoted as a result of the synergistic actions of the different treatments on microbes (Lee et al. 2009). Manothermosonication is an emerging technique that combines heat and ultrasound at elevated pressure. Based on intensity, amplitude, and time of treatment, manothermosonication can be 6–30 times more effective in killing microorganisms (*Bacillus* species, *Sacchromyces cerevisae*) compared to thermal treatment given at same temperature. Different enzymes such as POX, lipase, lipoxygenase, protease, and pectin methylesterase have been tested for inactivation by manothermosonication (Demirdoven and Baysal 2009). Manothermosonication has been used to enhance the textural and functional properties of tomato juice and milk proteins (Lopez and Burgos 1995, Vercet et al. 2002). Ultrasound has also been used in combination with chlorine, and a strong bactericidal effect was observed (Blume and Neis 2005). Chlorine dioxide, when used with heat and ultrasound, destroyed *Salmonella* and *E. coli* cells in alfalfa seeds (Scouten and Beuchat 2002). The full potentials of ultrasound in food processing have yet to be tapped. There will continue to be progress made on design of improved and efficient equipment. Better understanding of the effect of the process on technological and functional properties will be crucial in identifying niche applications of the technology.

UV Irradiation

The nonionizing UV radiation in the wavelength range of 100–400 nm is widely used in food processing. The electromagnetic spectrum is classified into three groups, namely UV-A (315–400 nm), UV-B (280–315 nm), and UV-C (less than 280 nm). UV-C is particularly used because of its effective germicidal capacity. The wavelength of 253.7 nm is known to have the most lethal effect on microorganisms since photons are absorbed most by the DNA of microorganisms at this wavelength (Labas et al. 2005). UV light can be generated from various sources. The low pressure mercury vapor UV lamps are widely used as reliable and low cost sources of UV light (Ngadi et al. 2003). These lamps operate at the nominal total gas pressures of 102–103 Pa and their UV output is in the range of 0.2–0.3 W/cm (Koutchma 2009). More recently, high intensity lamps with enhanced potential for UV microbial inactivation are being developed. Pulsed UV systems (PUV) have been developed and have been shown to be more effective in inactivating bacteria. In these systems, alternating current is stored in a capacitor and the energy is discharged through a high-speed switch to form a pulse

of intense emission of light of about 100 μs durations. Some recent studies have reported application of PUV light for surface treatment of food products such as fresh-cut fruit, meats, and fish (Woodling and Moraru 2005, Ozer and Demirci 2006, Alothman et al. 2009, Oms-Oliu et al. 2009, Pombo et al. 2009). A prime goal of UV application in food processing is to reduce microbial load and achieve high-quality product with improved shelf life while maintaining sensory attributes. Some fresh-cut fruits and vegetables such as cantaloupe and fresh-cut melon treated with UV light yield better quality retention, since the treatment was effective in reducing microbial populations (Lamikanara et al. 2005, Artés-Hernández et al. 2010). The efficiency of the treatment depends on the structure of the fruit surface (Koutchma 2008). A reduction in microbial load was observed in juices from apple, guava, pineapple, and orange when treated with UV radiation (Keyser et al. 2008). Application of UV at 24 mW/cm^2 on apples inoculated with *Salmonella* and *E. coli* O157:H7 resulted in 3.3 log reduction (Yaun et al. 2004). In order to achieve high microbial inactivation, UV light should be applied for a sufficient time. Combination of UV and other minimal processing technologies can be used to improve microbial inactivation efficiency. Using modified atmosphere packaging (MAP; high concentrations of carbon dioxide) and UV together significantly reduced microbial population (Artés et al. 2009). Apart from antimicrobial action, UV may also influence the antioxidant activity of fresh-cut fruits and vegetables. An increase in the total phenol contents of fresh-cut tropical fruits such as banana and guava (Alothman et al. 2009), and enhanced flavonoid and antioxidant levels were observed in blueberries (Perkins-Veazie et al. 2008, Wang et al. 2009c) when the products were treated with UV irradiation. Gomez et al. (2010) reported changes in the color and mechanical compression behavior of apple cuts exposed to UV irradiation. Treated cuts showed accelerated browning, which the authors attributed to breakage of cellular membranes (plasmalemma and tonoplast). The phenomenon was also used to explain decrease in rupture stress and deformability indices for UV-treated samples during storage. This observation is curious as the action of UV on biological cells is traditionally attributed to changes in DNA modification. Pretreatment of apple cuts blanching or dipping in anti-browning solution were reported as effective in reducing quality changes and maintaining the original color of apple slices after UV treatment. Thus, the influence of UV on biological cells may be more complicated as previously thought. Improved understanding of the effect may open doors to innovative application of the technology.

Other Techniques

Various other novel techniques, photochemical (intense light pulses, etc.) and nonphotochemical processes are being used for minimal processing of fruits and vegetables. Electrolyzed water has been used to disinfect food surfaces. The pH of electrolyzed water can be raised or lowered by adding hydroxyl or hydrogen ion concentration. Decreased bacterial growth in fresh-cut cabbage was observed when sanitized with slightly acid electrolyzed water (Koide et al. 2009). Neutral Electrolyzed Water (NEW) was used to demonstrate the efficacy of NEW over Sodium

hypochlorite in inhibiting *Listeria monocytogenes*, *Salmonella, E. coli* O157:H7, and the bacteria *Erwinia carotovora* in lettuce and fresh-cut products (Abadias et al. 2008). Comparison of bacterial reduction potency of strongly acidic electrolyzed water (SAEW), sodium hypochlorite solution (NaOCl), and slightly acidic electrolyzed water (StAEW) yielded the following order: StAEW > NaOCl > SAEW (Issa-Zacharia et al. 2010). The level of implementation of these techniques at commercial scale has been limited.

QUALITY AND SAFETY CONSIDERATIONS: THE HURDLE CONCEPT

Although food safety is critical, it is known that quality is a top-of-mind consideration when consumers purchase food products. A successful processing technique must therefore not only ensure that the product is safe, it must also maintain appropriate quality attributes that can be acceptable by consumers. Thermal treatment is a broad-spectrum antimicrobial process. However, novel nonthermal or minimal processing techniques have been developed due to the potential of thermal processing to degrade nutritive quality and functional properties of foods. The individual use of most of the new techniques may not provide the inactivation level required for commercial processing. Recently, combined inactivation techniques of microorganisms have been widely investigated since a combination of different "hurdles" is a more effective means of inhibiting microorganisms than using each "hurdle" alone (Alakomi et al. 2002, Leistner 2000). The hurdle concept is based on the imposition of certain hurdles to restrict the growth of food spoiling microorganisms as illustrated in Figure 39.2. Any microbial inactivation factor can potentially be adapted as a hurdle. Nearly 60 potential hurdles have been identified for food preservation. The hurdles must be applied in a logical sequence to ensure safety of the food product. The resistance of different pathogens should be considered when a hurdle is the lone preservation factor. For instance, PEF as well as high-pressure treatment effectively inactivate bacteria and

Figure 39.2. Schematic of enhanced microbial inactivation using different hurdles in food processing.

yeast but are ineffective against bacterial and mold spores and some enzymes. Ultrasound is ineffective against wide-ranging pathogens. Although heating is the most broad-spectrum inactivation method, cells of *Clostridium botulinum* are highly resistant even to thermal treatment. Moreover, there is an inactivation threshold after which further hurdle application and energy input do not inactivate microorganisms or degrade nutritive quality of the treated foods.

A synergistic relationship between different nonthermal physical and chemical hurdles has been observed for both foods (Fielding et al. 1997, Raso et al. 1998, Dutreux et al. 2000, Heinz and Knorr 2000, Aronsson and Rönner 2001, Fernanda et al. 2001) as well as nonfoods liquids (wastes, poultry chiller water, and others) (Liltved et al. 1995, Unal et al. 2001, Larson and Mariñas 2003). Although the simultaneous application of different nonthermal technologies has been shown to have a significant bactericidal effect, thermal treatment may still be required to achieve the level of inactivation of different microorganisms necessary for practical use. Thus, combination of thermal treatment with PEF (thermoelectrical treatment), pressure (manothermal treatment), ultrasound (thermoultrasonication), irradiation (thermoradiation), and other hurdles have been reported (Raso et al. 1998, Hoover 2000, Aronsson and Rönner 2001, Kim et al. 2001, Ohshima et al. 2002). Synergistic bactericidal effects have also been observed between heat and ultrasound (Wrigley and Llorca 1992), heat and radiation (Schaffner et al. 1989), heat and nisin (Knight et al. 1999), high hydrostatic pressure and nisin (Ponce et al. 1998), and PEF and nisin (Calderón-Miranda et al. 1999). Some general approaches for understanding hurdle concept can be found in Barbosa-Canovas et al. (1998) and Leistner and Gorris (1995).

MICROBIAL STRESS

When microorganisms present in food encounter stress in the form of various hurdles, they undergo homeostasis. The organisms try to prevail over inclement conditions caused by hurdles, but metabolic exhaustion due to repair action leads to death of the microorganisms. However, when bacteria are under stress, they can become more resistant and synthesize stress shock proteins. These proteins play the role of molecular chaperons by folding distorted proteins into a shape that retains the cell functionality under stress (Hightower 1991). But if the food is exposed to different stresses simultaneously, the microorganism generates more shock protein using all the cell energy and dies due to metabolic exhaustion (Leistner 2000).

MULTITARGET PRESERVATION OF FOODS

Hurdle technology emphasizes intelligent combination of various preservation techniques. Leistner (1995) proposed concept of multitarget preservation of foods and suggested that different hurdles rather than having an accruing effect may have synergistic action. It has been suggested that different preservative factors of variable intensity be used for the synergistic action, instead of using a single high-impact preservative. These targets include cell components, enzymes, pH, water activity, redox potential,
etc. Barbosa-Canovas et al. (1998) suggested that the applicability of multitarget preservation approach is not only limited to traditional methods of food preservation, but also valid for emerging nonthermal technologies like HPP, PEF, etc. A lot of new research is being done using newer technologies, which are based upon the central idea of multitarget preservation.

LIMITATIONS OF HURDLE CONCEPT

Combination of two or more hurdles results in either additive, synergistic, or antagonistic effect. Addition and synergism justify the use of hurdle technology but some studies have shown the negative effect of using some hurdle combinations (Jordan et al. 1999, Casey and Condon 2002). The antagonistic phenomenon is related to the type of conditions, intensity of preservative action of each hurdle, and the type and nature of food to be minimally processed.

PACKAGING TECHNIQUES FOR MINMALLY PROCESSED FOODS

MAP

MAP is a method of preserving the fruits and vegetables by changing the composition of the air surrounding the food in a package. Different gas mixtures in varying concentrations are used in modifying the atmosphere inside the package. Generally, oxygen and carbon dioxide are used for packaging of minimally processed fruits and vegetables, but the potentials of other gases like nitrogen, carbon monoxide, and noble gases (Helium, Argon, and Neon) have also been realized (Sandhya 2010). Higher carbon dioxide and reduced oxygen levels have been found efficient in enhancing the shelf life and preventing the problem of enzymatic browning in fruits and vegetables. Generally, 15–20% CO_2 has been considered effective in preventing decay in fresh fruits and vegetables. In case of meat products, oxygen is used for retaining the red color of oxymyoglobin, but oxygen levels are reduced in other products to prevent oxidative rancidity and spoilage due to microbes. Very low oxygen or high concentration of carbon dioxide can initiate anaerobic respiration in the package, which may lead to formation of certain undesirable metabolites, harming the product's physiology (Soliva-Fortuny and Martin-Belloso 2003).

The essential characteristics for MAP packaging material are the gas permeability and water vapor transmission rate. Most common packaging materials include polyvinyl chloride, polypropylene, polyethylene, and polyethylene terephthalate (Mangaraj and Goswami 2009). These days, laminates or coextruded films are used for packaging. The traditional gas mixture configuration is not enough to prevent the deteriorative reaction if fruits and vegetables get wounded. Minimal processing up to some extent is responsible for initiating the tissue damaging. Also, the packaging materials used for MAP are prone to some limitations pertaining to textural, color, and permeability changes. Hence, as a solution, edible coatings are being seen as potential alternative to the MAP technique (Rojas-Grau et al. 2009). The advantages of edible coating are numerous, and con-

stantly improvements are being made by incorporating active ingredients like antioxidant, antimicrobials, antibrowning agents, etc. Edible coatings have been explained later in the chapter.

ACTIVE AND EDIBLE PACKAGING

Active packaging implies incorporation of certain additives that can enhance the shelf life, flavor, texture, etc. by interacting with the food product inside the package. These additives can be oxygen scavengers, carbon dioxide absorbers or generators, ethanol emitters, ethylene absorbers, and moisture absorbers (Ohlsson and Bengtsson 2002). Antioxidants and antimicrobial compounds are also used in the active packaging.

Inclusion of chemical or physical additives in packages may become a hindrance for consumer acceptance of packaged foods. The development of packaging techniques that use natural materials like edible coating is a potential alternative to the chemical-based packaging methods. Edible coating is applied on the surface of food by spraying, dipping, or brushing. Sources of edible coatings are polysaccharides, proteins, and lipids (Lin and Zhao 2007). Edible coatings help reduce water loss and delay ageing by allowing controlled and selective gas permeability through product. They are also environmentally friendly as they reduce synthetic packaging waste.

CONCLUSION

Minimally processed foods have become very popular with consumers. All the aspects related to minimally processed food, from processing to packaging, are witnessing an unprecedented continuous improvement. The combined treatment methods using thermal and nonthermal technologies have shown promising results. Updated knowledge of the different emerging techniques and how they might interact when combined may be critical in developing new and innovative processing strategies.

Separation Technology in Food Processing

John Shi, Sophia Jun Xue, Xingqian Ye, Yueming Jiang, Ying Ma, Yanjun Li, and Xianzhe Zheng

INTRODUCTION

Separation of one or more components from a complex mixture is a requirement for many operations and is extensively used in various applications in the food and biotechnology industries. Application of separation technologies is used either to recover high-value components from agricultural commodities, being an important operation for the production of food products such as oil and proteins, or especially for the development of health-promoting food ingredients and high value-added food products such as antioxidants and flavors. Separation processes are also used to remove contaminants and impurities from food materials. Separation, often known as "downstream processing," is totally devoted to the science and engineering principles of separation and purification. Over the last 20 years, separation

technologies in the food processing area have undergone an explosive growth. The competitive nature of the biotechnologies applied to the pharmaceutical and food industries for cost-effective manufacturing have provided much impetus for the development and use of new separation techniques on a large scale, but at a lower cost. Aside from the conventional separation techniques such as solvent and water extraction (solid–liquid contacting extraction or leaching), crystallization, precipitation, distillation, and liquid–liquid extraction, etc., have already been incorporated in basic food processing and well established and commercialized. A number of newer separation techniques as promising alternative methods for improved application in food engineering have been implemented on the commercial scale, including supercritical CO_2 fluid extraction, membrane-based separation, molecular distillation, and pressured low-polarity water extraction procedures. These newer techniques have made impressive advances in obtaining adequate segregations of components of interest with maximum speed, minimum effort, and minimum cost at as large a capacity as possible in production-scale processes. These techniques have been implemented for the purification of proteins, characterization of aromas, whey protein removal from dairy products, extraction of health-benefiting fish oil, and clarification of beverages including beer, fruit juices, and wine. The separation processes and technologies for high value-added products are based on their polarity and molecular size. Many potential high-value products can be developed from natural resources by different separation technologies and processes. Carotenoids, including lycopene, β-carotene, astaxanthins, and lutein, make up a world market nearing \$1 billion with a growth rate of about 3%. Therefore, efforts to utilize natural agricultural materials for the production of high value-added products, especially health-promoting foods and ingredients, are of great interest to the food and biotechnology industries.

MAIN SEPARATION PROCESSES IN FOOD INDUSTRIAL APPLICATIONS

Separation processes such as extraction, concentration, purification, and fractionation of nutrients or bioactive components from agricultural materials are the main processes used to obtain high-value end products. All separations rely on exploiting differences in physical or chemical properties of mixture of components. Some of the more common properties involved in separation processes are particles or molecular size and shape, density, solubility, and electrostatic charge. In some operations, more than one of these physical and chemical properties is involved. As a unit operation, the separation process plays a key function in the whole procedure for value-added food processing. The science of separation consists of a wide variety of processes, including mechanical, equilibrium, and chromatographic methods.

MECHANICAL SEPARATION PROCESSES

Centrifugation

The centrifugation process works to separate immiscible liquids or solids from liquids by the application of centrifugal force. A centrifuge is a spinning settling tank. The rapid rotation of the entire unit replaces gravity by a controllable centrifugal or radial force. Centrifugal separation is used primarily in solid–liquid or liquid–liquid separation processes, where the process is based on density difference between the solid or liquids. Centrifugation is typically the first step in which the suspended solids or liquids are separated from the fluid phase. Various designs of centrifuge are used in the food industry such as removal of solids from juice, beverage, fermentation broths, or dewatering of food materials. Most centrifugal processes are carried out on a batch basis. However, some automatic and continuous centrifuge equipment and process are applied in the food and biotechnology industry.

Filtration

Filtration is the separation of two phases, solid particles or liquid droplets, and a continuous phase such as liquid or gas, from a fluid stream by passing the mixture through a porous medium. Filtration finds applications through the food and biotechnology industries. Filtration is employed at various stages in food manufacture, such as the refining of edible oils, clarification of sugar syrups, fruit juice, vinegar, wine, and beer, as well as yeast recovery after fermentation. Filtration is also carried out to clarify and recover cells from fermentation broths in the biotechnology area.

Filtration can be classified into conventional and nonconventional filtrations. The conventional filtration process uses filtration media with coarse selectivity and cannot separate similar size particles. It usually refers to the separation of solid, immiscible particles from liquid streams. Conventional filtration is typically the first step in which the suspended solids are separated from the fluid phase.

Membrane Separation

Nonconventional filtration processes use membrane separation technology. This nonconventional filtration has evolved into a quite sophisticated technique with the advent of membranes whose pore size and configuration can be controlled to such a degree that the filtration area is maximized while keeping the total volume of the unit small. A membrane separation process is based on differences in the ability to flow through a selective barrier (membrane) that separate two fluids. It should permit passage of certain components and retain certain other components of the mixture. Membrane separation processes are classified as microfiltration, ultrafiltration, and reverse osmosis according to the pore size of the membranes.

Ion-Exchange and Electrodialysis

Ion-exchange and electrodialysis are distinct separation processes, but both processes are based on the molecular electrostatic charge.

Electrodialysis

The electrodialysis process is based on the use of ion-selective membranes, which are sheets of ion-exchange resin. The process permits the separation of electrolytes from nonelectrolytes in solution and the exchange of ions between solutions. The electrodialysis process is used to separate ionic species in the food and biotechnology industries. In the electrochemical separation process, a gradient in electrical potential is used to separate ions with charged, ionically selective membranes. The electrodialysis process is used widely to desalinate brackish water to produce potable water. The process is also used in the food industry to deionize cheese whey and in a number of pollution-control applications.

Ion-Exchange

The ion-exchange process is defined as the selective removal of charged molecules from one liquid phase by transfer to a second liquid phase by a solid ion-exchange material. The mechanism of absorption is electrostatic opposite charges on the solutes and ion-exchanger. The feed solution is washed off, followed by desorption, in which the separated species are recovered back into solution in a purified form. The main areas using it are sugar, dairy (separation of protein, amino acids), and water purification. Ion-exchange processes are also widely used in the recovery, separation, and purification of biochemicals, monoclonal antibodies, and enzymes.

Solid/Solid Separation

Solid/solid separation is a mechanical separation such as in a milling separation facility. Solid/solid separation can be achieved on the basis of particle size from the sorting of large food units down to the molecular level. Shape, moisture content, electrostatic charge, and specific gravity may affect the separation process. Screening of materials through perforated beds (wire mesh, cloth screen) produces materials of more uniform particle size. For example, screening is usually used to sort and grade many food materials such as fruits, vegetables, and grains. A wide range of geometric designs of flat bed and rotary fixed aperture screens are used in the food industry.

Sedimentation (Precipitation or Settling)

The sedimentation process is based on gravitational settling of solids in liquids. Sedimentation processes are slow and are widely used in water and effluent treatment processes.

Magnetic Separation

Magnetic separation relies on the behavior of individual particles under the influence of magnetic forces. When exposed to a magnetic field, ferromagnetic materials are attracted along lines of magnetic force from points of lower magnetic field intensity to points of higher magnetic field intensity.

EQUILIBRATION SEPARATION PROCESSES

The following processes are the unit operations commonly observed in the food industry that involve equilibrium between solid and liquid phases.

Adsorption

Absorption is a process whereby a substance (absorbate or sorbate) is accumulated on the surface of a solid. Absorption process is used to recover and purify the desired products from a mixture of liquids. Adsorption is used for decolorization and enzyme and antibiotic recovery. Liquid-phase adsorption is usually used for the removal of contaminants present at low concentrations in process streams.

Evaporation

Evaporation is the concentration of a solution by evaporating water or other solvents. The process is largely dependent on the heat sensitivity of the material. Boiling temperatures can be lowered under vacuum. Most commercial evaporators work in the range 40–90°C and minimize the residence time in the heating zone, for the concentration of heat-sensitive liquid foods and volatile flavor and aroma solutions. The final product after an evaporation process is usually in the liquid form.

Crystallization

Crystallization processes can be used to separate a liquid material from a solid. Crystallization separates materials and forms solid particles of defined shape and size from a supersaturated solution by creating crystal nuclei and growing these nuclei to the desired size. Crystallization is often used in a high-resolution, polishing, or confectioning step during the separation of biological macromolecules. Crystallization can be affected by either cooling or evaporation to form a supersaturated solution in which crystal nuclei formation may occur. Sometimes, it is necessary to seed the solution by addition of solute crystals. Batch and continuous operations of crystallization processes are used in commercial food production.

Dewatering (Dehydration or Drying)

Dewatering is the process applied to separate water (or volatile liquids) from solids, slurries, and solutions to yield solid products.

Extraction

Solvent extraction is a method for a solvent–solvent or solvent–solid contacting operation.

Solid–Liquid Extraction, e.g., Organic–Aqueous Extraction

The solid is contacted with a liquid phase in the process called solid–liquid extraction or leaching in order to separate the desired solute constituent or to remove an unwanted component from the solid phase. Solid–liquid extraction or leaching is a

separation process affected by a fluid involving the transfer of solutes from a solid matrix to a solvent. It is an operation extensively used to recover many important high-value food components such as oil from oilseeds, protein from soybean meal, phytochemicals from plants, etc. Solid–liquid extraction is also used to remove undesirable contaminants or toxins from food materials.

Liquid–Liquid Extraction, e.g., Two-Phase Aqueous Extraction

Liquid–liquid extraction separates a dissolved component from its solvent by transfer to a second solvent, mutually nonmiscible with the carrier solvent. The liquid–liquid extraction as a technology has been used in the antibiotics industry for several decades and now is recognized as a potentially usefully separation step in protein recovery on a commercial production.

Supercritical Fluid Extraction

Supercritical CO_2 fluid extraction is mostly for high value-added products that are sensitive to heat, light, and oxygen. The extraction process is implemented in a supercritical region where the extraction fluid (e.g., CO_2) has liquid-like densities and solvating strengths but retains the penetrating properties of a gas.

Distillation

Distillation is a physical separation process used to separate the components of a solution (mixture) that contains more components in the liquid mixture, by the distribution of gas and liquid in each phase. The principle of separation is based on the differences in composition between a liquid mixture and the vapor formed from it, because each substance in the mixture has its own unique boiling point.

Chromatographic Methods

Chromatography is a separation technique based on the uneven distribution of analytes between a stationary (usually a solid) and a mobile phase (either a liquid or a gas). Chromatography can be conducted in two or three dimensions. Two-dimensional chromatography, for example paper chromatography, is almost solely used for analytical purposes. Column chromatography separation is the most common form of chromatography used in the food processing field for further purification of high value-added components. Many variations exist on the basic chromatography methods. Some well-established methods are listed below.

Liquid–Solid Absorption Chromatography (e.g., Hydroxyapatite)

In absorption, molecules in a fluid phase concentrate on a solid surface without any chemical change. Physical surface forces from the solid phase attract and hold certain molecules (substrate) from the fluid surrounding the surface.

Affinity Chromatography

Affinity chromatography exploits the natural, biospecific interactions that occur between biological molecules. These interactions are very specific and because of this affinity separation process are very high resolution methods for the purification of food products such as proteins. Affinity chromatography has a gel surface that is covered with molecules (ligand) binding a particular molecule or a family of molecules in the sample.

Size-Exclusion Chromatography

Size-exclusion chromatography, also known as gel permeation chromatography when organic solvents are used, is used to control the pore size of the stationary phase so as to separate molecules according to their hydrodynamic volume and molecular size.

Ion-Exchange Chromatography

Ion-exchange chromatography and a related technique called ion-exclusion chromatography are based on differences in the electric charge density of their molecules during charge–charge interaction of molecules. It is a variation of absorption chromatography in which the solid adsorbent has charged groups chemically linked to an inert support. Ion-exchange chromatography is usually used for recovery and purification of amino acids, antibiotics, proteins, and living cells.

Hydrophobic Interaction Chromatography

Hydrophobic interaction chromatography is based on a mild adsorption process, and separates solutes by exploiting differences in their hydrophobicity.

Reverse Phase Chromatography

Reverse phase chromatography is based on the similar principles of hydrophobic interaction chromatography. The difference is that the solid support is highly hydrophobic in reverse phase chromatography, which allows the mobile phase to be aqueous.

ENGINEERING ASPECTS OF SEPARATION PROCESSES

Much of the recent process development for the separation of valuable components from natural materials has been directed toward high value-added products. For the recovery of valuable components from raw materials, applications of separation technologies to recover major or minor components from agricultural commodities is usually a solid–liquid contacting operation. As research moves into commercial production, there is a great need to develop scalable and cost-effective methods of separation technologies. The successful and effective development of separation technologies is a critical issue in the chain of value-added processing of agricultural materials such as developments in functional food ingredients, nutrients, and nutraceuticals.

Separation operations are interphase mass transfer processes because they involve certain heat, mass, and phase transfers, as well as chemical reactions among food components. The engineering properties of the targeted food components via separation systems include separation modeling, simulations, optimization control studies, and thermodynamic analyses. The principles of mass conservation and component transfer amounts are used to analyze and design industrial processes. Molecular intuition and a thermodynamic approach constitute powerful tools for the design of a successful separation process. The following issues of engineering properties are important for process optimization and simulation.

1. Chemical equilibration—binary, ternary, and multicomponent systems in solid–liquid contacting operation,
2. Diffusivity (pressure diffusion, thermal diffusion, gaseous diffusion) and convection,
3. Solubility of targeted components under different separation operating conditions,
4. Iso-electric points and charge dependence on pH,
5. Chemical interaction kinetics (colloid formation and affinity),
6. Physical properties of particles of the food material,
7. Flux and fouling properties in membrane separation processes,
8. Solvent selection, recycling, and management,
9. Nature of solvents, optimum composition of mixed solvents for certain nutrient separations, and solvent residues in food products are factors to be optimized.
10. Some solvent treatments such as evaporation, concentration, de-watering, de-coloring, toxicological analyses, waste minimization, recycling, and disposal are necessary.

SEPARATION SYSTEM DESIGN

TECHNICAL REQUEST FOR A SEPARATION SYSTEM

An important consideration in determining the appropriateness of a separation technique and system is the actual purity requirement for the end products. In design of organic solvent (toxic chemical)-free separation technologies and systems, there are several essential technical approach requirements for technology advances, such as combination of new techniques available for system optimization, product design and reasonable separation and purification steps, environmentally friendly process, less air pollution and industrial waste (e.g., energy, greenhouse gases emission, reduction of waste water production), and economic feasibility and raw material selection.

FOOD QUALITY AND SEPARATION SYSTEM

The major issues related to product quality after separations are the impacts of processing on bioactive compounds and the nutritional aspects of foods, as well as the quality characteristics. To meet the food safety regulations, no toxic chemical solvent residues are permitted in the end food products, e.g., "green" food products. Nutrition and health regulations must be met. Also important are a high stability of nutrients and bioactive components, processes operating at low temperatures to reduce thermal effects, processes that exclude light to reduce light induced (UV) irradiation effects, and processes that exclude oxygen to reduce oxygen effects. And the final product must maintain uniformity and quality consistency, and purity can meet food grade or pharmaceutical grade requirements.

SCALING UP TECHNOLOGY FOR INDUSTRIAL PRODUCTION

Scaling up of a natural product separation process is by no means a simple affair. The enormous variations from process to process necessitate careful attention to details at all stages of product development. When the technology in a food process is designed for industrial-scale production, an important area for consideration is the balance of capital and operating costs as the scale of the separation operation increases. Scale up of separation technology also involves optimization with respect to increasing the efficiency of each stage, giving rise to increasing demands on the accuracy of the assay system.

NEW TECHNOLOGY DEVELOPMENT

Extraction of health-promoting components from plant materials has usually been accomplished by conventional extraction processes such as solid–liquid extractions employing methanol, ethanol, acetone, or hexane and also through steam distillation or evaporation processes to remove solvents from extracts. Currently, the demand for natural bioactive compounds is increasing due to their use by the functional food and pharmaceutical industry. Thus, there has been increasing interest in the use of environmentally friendly "green" separation technologies able to provide high quality–high bioactivity extracts while precluding any toxicity associated with the solvent. Some of the motivations to employ "green" separation technologies as a viable separation technique are (a) tightening government regulations on toxic-chemical solvent residues and pollution control, (b) consumers' concern over the use of toxic chemical solvents in the processing, and (c) increased demand for higher quality products that traditional processing techniques cannot meet.

One of the most important considerations in developing new extraction processes is the safety aspect. In this sense, a variety of processes involving extractions with supercritical CO_2 fluid extraction, membrane-based separation, molecular distillation, and pressured low-polarity water extraction, etc., are generally recognized as "green" separation technology and are considered clean and safe processes to meet the requirements (Ibáñez et al. 1999, Fernandez Perez et al. 2000, Herrero et al. 2006, Chang et al. 2008). They have been developed and are regarded as innovative emerging separation technologies that meet food quality and safety requirements. These processes can be used to solve some of the problems associated with conventional organic solvent-oriented separation processes. Operation parameters and other factors related to the quality of the original plant, its geographic origin, the harvesting date, its storage, and its pretreatment process prior to extraction also influence the

separation operations and the final composition of the extracts obtained.

SUPERCRITICAL CO₂ FLUID TECHNOLOGY

Changes in food processing practices and new opportunities for innovative food products have spurred interest in supercritical CO_2 fluid extraction. Supercritical CO_2 fluid technology has been widely used to extract essential oils, functional fatty acids, and bioactive compounds, and also been applied in recently developed extraction and fractionation for carbohydrates (Glisic et al. 2007, Shi et al. 2007a, Montañés et al. 2008, Mitra et al. 2009, Montañés et al. 2009, Sanchez-Vicente et al. 2009, Shi et al. 2010a, 2010b). Supercritical CO_2 fluid extraction is a novel separation technique that utilizes the solvent properties of fluids near their thermodynamic critical point. Supercritical CO_2 is being given a great deal more attention as an alternative to organic chemical industrial solvents, and increased governmental scrutiny and new regulations restricting the use of common industrial solvents such as chlorinated hydrocarbons. It is one of the "green" separation processes that provides nontoxic and environmentally friendly attributes and leaves no traces of any toxic chemical solvent residue in foods.

When CO_2 fluid is forced into a pressure and temperature above its critical point (Fig. 40.1), CO_2 becomes a supercritical fluid. Under these conditions, various properties of the fluid are placed between those of a gas and those of a liquid. Although the density of a supercritical CO_2 fluid is similar to a liquid and its viscosity is similar to a gas, its diffusivity is intermediate between the two states. Thus, the supercritical state of a fluid has been defined as a state in which liquid and gas are indistinguishable from each other or as a state in which the fluid is compressible (i.e., similar behavior to a gas), even though possessing a density similar to that of a liquid and with similar

solvating power. Because of its different physicochemical properties, supercritical CO_2 provides several operational advantages over traditional extraction methods. Because of their low viscosity and relatively high diffusivity, supercritical CO_2 fluids have better transport properties than liquids. They can diffuse easily through solid materials and therefore give faster extraction yields. One of the main characteristics of a supercritical fluid is the possibility of modifying the density of the fluid by changing its pressure and/or its temperature. Since density is directly related to solubility (Raventós et al. 2002, Shi and Zhou 2007, Shi et al. 2009a), by altering the extraction pressure, the solvent strength of the fluid can be modified.

The characteristic traits of CO_2 are inertness, nonflammability, noncorrosiveness, inexpensive, easily available, odorless, tasteless, and environmentally friendly. Its near-ambient critical temperature makes it ideal for thermolabile natural products (Mendiola et al. 2007). CO_2 has its favorable properties and the ease of changing selectivity by the addition of a relatively low amount of modifier (co-solvent) such as ethanol and other polar solvents (e.g., water). CO_2 may be considered the most desirable supercritical fluid for extracting natural products for food and medicinal uses (Shi et al. 2007b, Kasamma et al. 2008, Shi et al. 2009b, Yi et al. 2009). Other supercritical fluids, such as ethane, propane, butane, pentane, ethylene, ammonia, sulphur dioxide, water, chlorodifluoromethane, etc., are also used in supercritical fluid extraction processes.

In a supercritical CO_2 fluid extraction process, supercritical CO_2 fluid has a solvating power similar to organic liquid solvents and a higher diffusivity, with lower surface tension and viscosity. The physicochemical properties of supercritical fluids, such as the density, diffusivity, viscosity, and dielectric constant, can be controlled by varying the operating conditions of pressure and temperature or both in combination (Tena et al. 1997, Shi et al. 2007a, 2007b, 2007e, Kasamma et al. 2008, Shi et al. 2009b). The separation process can be affected by simply changing the operating pressure and temperature to alter the solvating power of the solvent. After modifying CO_2 with a co-solvent, the extraction process can significantly augment the selective and separation power and in some cases extend its solvating powers to polar components (Shi et al. 2009a).

Supercritical CO_2 fluid extraction is particularly relevant to food and pharmaceutical applications involving the processing and handling of complex, thermo-sensitive bioactive components, and an increased application in the areas of nutraceuticals, flavors, and other high-value items such as in the extraction and fractionation of fats and oils (Reverchon et al. 1992, Rizvi and Bhaskar 1995), the purification of a solid matrix, separation of tocopherols and antioxidants, removal of pesticide residues from herbs, medicines, and food products, the detoxification of shellfish, the concentration of fermented broth, fruit juices, essential oils, spices, coffee, and the separation of caffeine, etc. (Perrut 2000, González et al. 2002, Miyawaki et al. 2008, Martinez et al. 2008, Liu et al. 2009a, 2009b).

This technology has been successfully applied in the extraction of bioactive components (antioxidants, flavonoids, lycopene, essential oils, lectins, carotenoids, etc.) from a variety of biological materials such as hops, spices, tomato skins, and

other raw or waste agricultural materials (Kasamma et al. 2008, Shi et al. 2009a, Yi et al. 2009, Huang et al. 2010, Shi et al. 2010a, 2010b, Xiao et al. 2010). The scale up of some supercritical extraction processes have already proven to be possible and are in industrial use.

The process requires intimate contact between the packed beds formed by a ground solid substratum (fixed-bed of extractable material) with supercritical CO_2 fluid. During the supercritical extraction process, the solid phase comprising of the solute and the insoluble residuum (matrix) is brought into contact with the fluid phase, which is the solution of the solute in the supercritical CO_2 fluid (solvent). The extracted material is then conveyed to a separation unit.

Process Concept Schemes

The physicochemical properties of the supercritical fluids are crucial to the understanding of the process design calculation and modeling of the extraction process. Therefore, selectivity of solvents to discriminate solutes is a key property for the process engineer. Physical characteristics such as density and interfacial tension are important for separation to proceed; the density of the extract phase must be different from that of the raffinate phase and the interfacial properties influence coalescence, a step that must occur if the extract and raffinate phase are to separate. The supercritical state of the fluid is influenced by temperature and pressure above the critical point. The critical point is the end of the vapor–liquid coexistence curve as shown on the pressure–temperature curve in Figure 40.1, where a single gaseous phase is generated. When pressure and temperature are further increased beyond this critical point, it enters a supercritical state. At this state, no phase transition will occur, regardless of any increase in pressure or temperature, nor will it transit to a liquid phase. Hence, diffusion and mass transfer rates during supercritical extraction are about two orders of magnitude greater than those with solvents in the liquid state.

Substances that have similar polarities will be soluble in each other, but increasing deviations in polarity will make solubility increasingly difficult. Intermolecular polarities exist as a result of van der Waals forces, and although solubility behaviors depend on the degree of intermolecular attraction between molecules, the discriminations between different types of polarities are also important. Substances dissolve in each other if their intermolecular forces are similar or if the composite forces are made up

in the same way. Properties such as the density, diffusivity, dielectrical constant, viscosity, and solubility are paramount to supercritical extraction process design. The dissolving power of SCF depends on its density and the mass transfer characteristic, and is superior due to its higher diffusivity and lower viscosity and interfacial tension than liquid solvents.

Although many different types of supercritical fluids exist and have many industrial applications, CO_2 is the most desirable for SCE of bioactive components. Table 40.1 shows some physical properties of compressed (20 MPa) supercritical CO_2 at 55°C as compared to some condensed liquids that are commonly used as extraction solvents at 25°C. It should be noticed that supercritical CO_2 exhibits similar density as those of the liquid solvents, while being less viscous and more highly diffusive. This fluid-like attribute of CO_2 coupled with its ideal transport properties and other quality attributes outlined above make it a better choice over other solvents.

The specific heat capacity (C_p) of CO_2 rapidly increases as the critical point (31.1°C temperature, 7.37 MPa pressure, and 467.7 g/L flow rate) is approached. Like enthalpy and entropy, the heat capacity is a function of temperature, pressure, and density (Mukhopadhyay 2000). Under constant temperature, both the enthalpy and entropy of supercritical CO_2 decreases with increased pressure and increases with temperature at constant pressure. The change in specific heat as a result of varying the pressure and temperature is also dependent on density. For example, under constant temperature, specific heat increases with increasing density up to a certain critical level. Above this critical level, any further increase in density reduces the specific heat.

Process System

The supercritical CO_2 fluid extraction process is governed by four key steps: extraction, expansion, separation, and solvent conditioning. The steps are accompanied by four generic primary components: extractor (high pressure vessel), pressure and temperature control system, separator, and pressure intensifier (pump; Fig. 40.2). Raw materials are usually ground and charged into a temperature-controlled extractor forming a fixed bed, which is usually the case for a batch and single-stage mode (Shi et al. 2007a, 2007b, Kasamma et al. 2008).

The supercritical CO_2 fluid is fed at high pressure by means of a pump, which pressurizes the extraction tank and also
Figure 40.2. Schematic diagram of a typical single-stage supercritical fluid extraction system with CO_2.

circulates the supercritical medium throughout the system. Figure 40.2 shows an example of a typical single-stage supercritical CO_2 fluid extraction system. Once the supercritical CO_2 and the feed reach equilibrium in the extraction vessel, through the manipulation of pressure and temperature to achieve the ideal operating conditions, the extraction process proceeds. The mobile phase consisting of the supercritical CO_2 fluid and the solubilized components is transferred to the separator where the solvating power of the fluid is reduced by raising the temperature and/or decreasing the pressure of the system. The extract precipitates in the separator while the supercritical CO_2 fluid is either released to the atmosphere or recycled back to the extractor. In the case where highly volatile components are being extracted, a multistage configuration may have to be employed as shown in Figure 40.3 (Shi et al. 2007a, 2007b, Kasamma et al. 2008).

The processes described above are semi-batch continuous processes where the supercritical CO_2 flows in a continuous mode while the extractable solid feed is charged into the extraction vessel in batches. In commercial-scale processing plants, multiple extraction vessels are sequentially used to enhance process performance and output. Although the system is interrupted at the end of the extraction period, when the process is switched to another vessel prepared for extraction, the unloading and/or loading of the spent vessels can be carried out while extraction is in progress, reducing the downtime and improving the production efficiency.

A semi-continuous approach on a commercial scale uses a multiple stage extraction processes that involve running the system concurrently by harnessing a series of extraction vessels in tandem, as shown in Figure 40.4. In this system, the process is not interrupted at the end of extraction period for each
Figure 40.3. Schematic diagram of supercritical fluid extraction system used to fractionate bioactive components from plant matrix using supercritical carbon dioxide.
Figure 40.4. Schematic diagram of commercial scale multistage supercritical fluid extraction system used to fractionate bioactive components. The symbol "Ƶ" is pressure valves and "Ⓦ" is heat exchangers.

vessel, because the process is switched to the next prepared vessel by control valves for extraction while unloading and/or loading the spent vessels. Thus, supercritical CO_2 technology is available in the form of single-stage batch that could be upgraded to multistage semi-continuous batch operations coupled with a multi-separation process. The need to improve the design into truly continuous modes is growing. Supercritical CO_2 fluid extraction could be cost-effective under large-scale production.

Industrial Applications

Large-scale supercritical CO_2 fluid extraction has become a practical process for the extraction of high-value products from natural materials. The solvating power of supercritical CO_2 fluids is sensitive to temperature and pressure changes; thus, the extraction parameters may be optimized to provide the highest possible extraction yields with maximum antioxidant activity for health-promoting components in bioactive extraction production (Kasamma et al. 2008, Chen et al. 2009, Yi et al. 2009b).

A supercritical CO_2 fluid extraction process offers the unique advantage of adding value to agricultural waste by extracting bioactives from agricultural by-products, which are then used for the fortification of foods and other applications. Its drawbacks are the difficulties in extracting polar compounds and its difficulty of extracting compounds from a complex matrix where the phase interaction with the intrinsic properties of the product inhibits its effectiveness. Some drawbacks can be ameliorated by using small amounts of food-grade co-solvents (less than 10%) to approach the high extraction efficiency (Shi et al. 2009a). However, much investigation is required to understand the solvation effects on the targeted bioactive components being extracted. The CO_2 density, pressure, and temperature have

been noted to have great impacts on the results of the extraction process. By understanding the effect of the parameters that influence the extraction process, the conditions may be set to optimize yield and cost efficiency. When determining the parameters that should be used to maximize yields and solubility of the targeted components, many researchers attempted to use conditions that may be applicable in large-scale applications (Shi et al. 2007f, Kasamma et al. 2008). For example, nontoxic co-solvents and modifiers could be acceptable for food processing; therefore, a number of researchers have opted to use food-grade co-solvents and modifiers in extraction processes (Shi et al. 2009a). The nature of the material used as a source of high-value components, such as health-promoting components, governs the availability of the compounds for the extraction process. The presence of other components such as lipids may impede the process or elevate costs due to an elongated extraction time.

Although a high temperature in the extraction process generally increases the solubility of components in supercritical CO_2 fluids, the conditions under which thermally labile targeted compounds are negatively affected should be considered (Shi et al. 2007a, 2007b, 2007e). The intensity and the length of heat processing affect the health-promoting properties of bioactives. Therefore, ideally, the extraction time and temperature should be minimized. Minimizing such conditions also leads to a more economically viable process (Shi et al. 2007f, Kasamma et al. 2008). Excessively high flow rates may reduce the contact time between the solute and the solvent and restrict the fluid flow in the sample if it becomes compacted. The optimal flow rate appears to vary with the targeted molecule, relatively high flow rates having a negative effect on some components. Raising the pressure increases extraction yields.

Sample matrix is an important parameter that influences the solubility and mass transfer process during SCE. Properties such

as particle shape and size distribution, porosity and pore size distributions, surface area, and moisture content influence solubility and mass transfer. The presence of water (moisture content) in the sample matrix during supercritical extraction also has an effect on the extraction outcome. In order to improve the yield and quality of the extracted high-value food components from raw material, a pretreatment of the raw material is an essential process (Yang et al. 2008, Zheng et al. 2009, Nagendra et al. 2010). Cell disruption is the most important pretreatment, and this procedure can be conducted by several processes such as mechanical, ultrasonic, high electronic field pulse, and nonmechanical treatments. With improved processing conditions and reduced cost, high-value components extracted from natural materials by supercritical CO_2 extraction process will become even more economical at high throughput.

Membrane-Based Separation Technology

Membrane-based technology is a rising separation technology. At present, more and more fields use membrane technology to separate the fluids and get good results. With the principal development of membrane technology, the applications are expanding much wider and the technology brings remarkable economic benefits. Now, many countries in the world have noticed the importance of membrane technology in the food processing field, especially since we are short of energy and resources and the deteriorating environment all exist in our lifetime. So, industries regard membrane-based separation technologies as important technologies in food processing areas.

The common membrane-based separation process is usually run under pressure. A membrane can be described as a thin barrier between the two bulk phases, and it is either a homogeneous phase or a heterogeneous collection of phases. In membrane separations, each membrane has the ability to transport one component more readily than the others because of differences in physical and chemical properties between the membrane and the permeating components. Furthermore, some components can freely permeate through the membrane, while others will be retained. The stream containing the components that pass through the membrane is called the permeate, and the stream containing the retained components is called the retentate. The flow of material across a membrane is kinetically driven by the application of pressure concentration, vapor pressure, hydrostatic pressure, or electrical potential (Mulder 1996, Cheryan 1998).

Membrane separation technology adopts a selective multi-hole membrane as the separation medium. The separated fluid, driven by the outside pressure, goes through the surface of the membrane with different pore sizes. The molecules will pass the membrane but larger molecules will be rejected. Therefore, the fluid can be separated into different molecular weights with high efficiency (Cheryan 1998).

Compared with the traditional separation process technologies, membrane-based separation processes can run under normal temperatures, so are especially good for separating and concentrating heat-sensitive materials such as juices, enzymes, or phytochemicals (Vaillant et al. 2001, Enevoldsen et al.

2007, Pouliot 2008). Moreover, membrane-based processes are energy-efficient processes that do not involve phase change or heat input; thus, the processes do not require ancillary equipment such as heat generator, evaporator, and condenser. They offer ease of operation and great flexibility, and do not require the addition of any chemical agents. The process also provides for minimal thermal degradation, occurs at ambient temperatures, and is used both to filter molecular-sized particulates and also to concentrate an isolate of interest, such as lycopene. Determination of the optimum operating conditions is vital importance.

Membrane-based processes are usually more energy efficient than distillation, adsorption, and chromatography. Furthermore, membrane-based separation has the advantage of compatibility with a wide range of solvents and chemical products, an ability to process thermally sensitive compounds and easy amenability to automation. These advantages open up several possibilities of membrane application in the production of bioactive compounds in the areas of energy-efficient pre-concentration of dilute solutions, fractionation of diverse classes of compounds from complex mixtures, recovery of intermediates, and recycling of solvents. The challenges posed by a membrane-based separation process are limited selectivity, fouling leading to performance decline, and a necessary and occasionally difficult periodic cleaning process. The performance of a membrane can be distinguished by two simple factors: flux (or product rate) and selectivity through the membrane. Flux is defined as the permeation capacity that refers to the quantity of fluid permeating per unit area of membrane per unit time. Flux depends linearly on both the permeability and the driving force. The flux also depends inversely upon the thickness of the membrane (Yang et al. 2001, Bhanusali and Bhattacharyya 2003, Kertész et al. 2005).

Figure 40.5 shows a classification of various separation-based processes that are based upon particle or molecular size. The five major membrane separation processes, including microfiltration, ultrafiltration, nanofiltration, reverse osmosis, and electrodialysis, cover a wide range of particle sizes according to the

Membrane separation

Microfiltration (MF)

Ultrafiltration (UF)

Nano filtration (NF)

Reverse osmosis (RO)

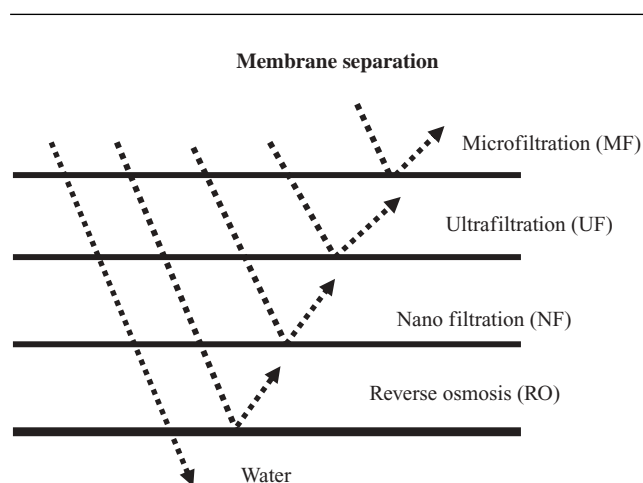
Water


Figure 40.5. Schematic diagram of membrane molecular cut property.

Table 40.2. Size of Materials Retained, Driving Force, and Type of Membrane

Process	Size of Materials Retained	Driving Force	Type of Membrane
Microfiltration	0.2–10 μm (microparticles)	Pressure difference (<2 bar)	Porous
Ultrafiltration	1–100 nm MWCO 10^3–10^6 Da (macromolecules)	Pressure difference (1–10 bar)	Microporous
Nanofiltration	0.5–5 nm (molecules)	Pressure difference (10–100 bar)	Microporous
Reverse osmosis	<2 nm MWCO 10^3 Da (molecules)	Pressure difference (10–100 bar)	Nonporous
Dialysis	1–3 μm (molecules)	Concentration difference	Nonporous or microporous
Electrodialysis	<1 nm (molecules)	Electrical potential difference	Nonporous or microporous

separation medium. The technology involves separating components from fluid streams by means of forcing the stream to flow under pressure over the surface of the membrane. Membrane properties (pore size, membrane material, and membrane configuration) and operating conditions (pressure, temperature, and feed velocity) play important roles for successful separation (Table 40.2). The introduction of cross-flow membrane system made large-scale continuous separation possible. The technology enables processors to concentrate, fractionate, and purify products simultaneously. The operation is usually conducted at ambient temperature, although they also have the capability to be run at higher or lower temperatures.

Microfiltration

The microfiltration membrane separation process is the most common pressure-driven membrane separation process and is defined as the separation of a retained particle size between 0.2 and 10 μm by the membrane. Two principal types of membrane filters are used: depth filters and screen filters, running at very low pressures owing to the open structure of the membranes. On the basis of the multi-hole membrane, microfiltration can effectively remove suspended particles, bacteria, colloids, and solid proteins. The common membrane modules include spiral-wound membranes, plate and frame membranes, tubular membranes, and hollow fiber membranes.

Ultrafiltration

Ultrafiltration is a pressure-driven filtration separation occurring on a molecular scale and can separate high-molecular weight solutes from a solvent, typically retaining macromolecules with a molecular weight cutoff of more than 1000 Da. The pore size of an ultrafiltration membrane normally is from 0.001 to 0.02 μm in order to provide purification, separation, and concentration. The membranes used in this process have a much smaller pore size for solvent passage than do microfiltration membranes, with a relatively small pore area per membrane surface area.

By using an ultrafiltration membrane with a different pore size, we can separate the contents in the solution with different molecular weight and shape, such as the purification and concentration of enzymes, proteins, cells, pathogenic organisms, and polysaccharides, and the clarification and decolorizations for

antibiotic fermentation (Li et al. 2004, Feins and Sirkar 2005, Krstić et al. 2007, Susanto et al. 2008, Cuellar et al. 2009). Ultrafiltration mainly has the following advantages: steady high permeated flux, resists free chlorine, wide range for pH and temperature, easy operation, low energy and operation cost, less pollution discharge, and compact equipment.

Ultrafiltration is used to separate solvents from solutions of very large molecules, as well as the liquid from a suspension of colloidal solids. Ultrafiltration membranes are commercially fabricated in sheet, capillary, and tubular forms. The liquid to be filtered is forced into the assemblage and dilute permeate passes perpendicularly through the membrane while concentrate passes out the end of the media. This may prove useful for the recovery and recycle of suspended solids and macromolecules. A key factor determining the performance of an ultrafiltration membrane is concentration polarization due to macromolecules being retained on the membrane surface.

Nanofiltration

A nanofiltration membrane is between a reverse osmosis membrane and an ultrafiltration membrane in pore size, which can remove NaCl under 90% concentration. A reverse osmosis membrane has a high removal rate for nearly all solutes. But a nanofiltration membrane only has a high removal rate for the special contents. Nanofiltration membranes mainly remove the particle whose diameter is near 1 nm, with a molecular weight cutoff of 100~1000 Da. In the drinking water area, nanofiltration is used to deal with quite large inorganic ions such as Ca^{2+}, Mg^{2+}, peculiar smells, pigments, pesticides, synthesized surfactants, dissoluble organics, and vaporized rudimental materials (Bates 2000, Braeken et al. 2004, Baisali et al. 2007). The character of nanofiltration is that it holds the charge itself, so under low pressure, it can also have a high desalination rate. The greatest field for the nanofiltration is to soften and desalt brine water. Nanofiltration has some advantages, including good chemical stability, long life, and high rejection selectivity.

Reverse Osmosis

Reverse osmosis is a liquid/liquid separation process that uses a dense semipermeable membrane, highly permeable to water. A pressurized feed solution is passed over one surface of the

membrane, as long as the applied pressure is greater than the osmotic pressure of the feed solution. Reverse osmosis membranes have been widely applied in water treatment, such as desalting, pollution control, pure water treatment, and wastewater treatment. Reverse osmosis operates by diffusion from a solution. Under the high differential pressure across the membrane, the solvent from the solution actually dissolves in the material of the membrane, diffuses across it, and transfers out into the clean solvent on the other side. It is not a perfect separation, because the dissolved species from the feed solution have definite abilities to diffuse through it as well, but the diffusion coefficient for the solvent is so much higher than that for the solute that the separation is virtually complete. Reverse osmosis is often used to remove dissolved organics and metals. Thus, reverse osmosis, as a device solely required to separate sodium chloride from water in the early days, is now being used to reject a wider range of solutes.

Electrodialysis

Electrodialysis, an electrically driven membrane process, is commonly used to desalt solutions. Ions in aqueous solution can be separated using a direct current electrical driving force on an ion-selective membrane. Electrodialysis usually uses many thin compartments of solution separated by membranes that permit passage of either positive ions (cations) or negative ions (anions) and block passage of the oppositely charged ion. Cation-exchange membranes are alternatively stacked with anion-exchange membranes placed between two electrodes. The solution to be treated is circulated through the compartments and a direct current power source is applied. All cations gravitate toward the cathode (negatively charged terminal) and transfer through one membrane, while anions move in the opposite direction, thereby concentrating in alternating compartments. Electrodialysis is commonly used to recover spent acid and metal salts from plating rinse. It obviously is not effective for nonpolar solutions.

Membrane-Based Separation in Industrial Applications

Membrane-based processes offer many advantages in terms of lower energy consumption, higher selectivity, faster separation rate, and lower recovery costs (Cassano et al. 2008). There has been increasing interest in the use of membrane-based technologies in the food industry. Various designs of membrane-based separation equipment are used in the food industry (Figure 40.6). In the dairy industry, ultrafiltration is widely used to fractionate cheese whey and pre-concentrate milk for cheese making (Pouliot 2008). In sequential membrane processes, ultrafiltration may also be used as a membrane reactor to produce protein hydrolysate from protein isolate (Feins and Sirkar 2005, Charoenvuttitham et al. 2006, Sarkar et al. 2007, Annathur et al. 2010) and as a membrane fermenter to produce fuels and chemicals from reverse osmosis concentrates (Greenlee et al. 2009, Qu et al. 2009, Saxena et al. 2009). In sugar and corn syrup process-
Figure 40.6. The pilot scale membrane separation system.

ing, microfiltration and ultrafiltration are used for clarification to remove impurities (Singh and Cheryan 1994, Jaeger de Carvalho et al. 2008). In juice, wine, and beer processes, microfiltration and ultrafiltration not only remove insoluble solids to produce sparkling clear product, but also remove spoilage microorganisms, eliminating the need for pasteurization (Massot et al. 2008, Vaillant et al. 2008, Cassano et al. 2010). Ultrafiltration is also used to concentrate natural colorants and flavors (Nawaz et al. 2005, Nawaz et al. 2006, Shi et al. 2007d, Galaverna et al. 2008, Ren et al. 2008a, 2008b, 2008c).

The main operating problem of all membrane separation processes is that the membrane material eventually plugs, called fouling, causing the resistance to flow to increase. The plugging process is accentuated by the concentration polarization that occurs in the relatively quiescent fluid zone close to the membrane surface, as the species separated from previously processed fluids build up in this zone and interfere with fresh material trying to get to the surface.

Membrane-based separation is still evolving and finding more and more applications in a broad range of fields, and the

development of new membrane materials will strongly influence separation processes in the future. Because of the great advantages of membrane separation over conventional separation practices, the availability of the choice of membrane size (microfiltration, ultrafiltration, nanofiltration, reverse osmosis, pre-evaporation membrane, and distillation membrane), materials (polymeric and ceramic, hydrophilic and hydrophobic, symmetric and asymmetric), configurations (spiral wound, hollow fiber, and plate and frame), operation modes (dead-end and cross-flow, batch, semi-batch, and continuous), and membrane technology offers more selective, flexible, and efficient separations over a wide range of compounds. This technology will continue to gain recognition and acceptance in the food industry.

Pressurized Low-Polarity Water Extraction

Pressurized low-polarity water extraction, also known as subcritical water extraction (or hot water extraction, pressurized hot water extraction, superheated water extraction, or high-temperature water extraction), that is, extraction using hot water under pressure, has recently become a popular green processing technology and emerges as a promising extraction and fractionation technique for replacing the traditional extraction methods. The pressurized low-polarity water extraction is also used in sample preparation to extract organic contaminants from foodstuff for food safety analysis and solids/sediments for environmental monitoring purpose.

The pressurized low-polarity water extraction process is an environmentally friendly technique that can provide higher extraction yields from solid plant materials (Luque de Castro and Jiménez-Carmona 1998). Pressurized low-polarity water extraction is based on the use of water as an extractant in a dynamic mode, at temperatures between 100°C and 374°C (critical point of water, 221 bar and 374°C) and under pressure high enough to maintain the liquid state. The critical temperature and pressure of water are shown as a phase diagram in Figure 40.5 ($T_c = 374$°C, $P_c = 221$ bar or 22 MPa). The pressurized low-polarity water extraction process can maintain the water in the liquid form up to a temperature of 374°C and a pressure of 22.1 MPa (221 bar) (Haar et al. 1984, Hawthorne et al. 2000). A pressure of 5 MPa would be high enough to prevent the water from vaporizing at temperatures from 100°C to 250°C. Once pressure is high enough to keep water in a liquid state, additional pressure is not necessary as it has limited influence on the solvent characteristics of water. Increasing the water temperature from 25°C to 250°C causes similar changes in dielectric constant, surface tension, and viscosity (Kronholm et al. 2007, Brunner 2009). Pressurized low-polarity water extraction can easily solubilize organic compounds such as phytochemicals, which are normally insoluble in ambient water.

Pressurized low-polarity water extraction has the ability to selectively extract different classes of compounds, depending on the temperature used. The selectivity of subcritical water extraction allows for manipulation of the composition of the extracts by changing the operating parameters, with the more polar ones extracted at lower temperatures and the less polar compounds extracted at higher temperatures (Basile et al. 1998,

Ammann et al. 1999, Clifford et al. 1999, Miki et al. 1999, Kubatova et al. 2001, Soto Ayala and Luque de Castro 2001).

Process System

As shown in Figure 40.7, the instrumentation consists of a water reservoir coupled to a high-pressure pump to introduce the pressurized low-polarity water into the system, an oven, where the extraction cell is placed and extraction takes place, and a restrictor or valve to maintain the pressure. Extracts are collected in a vial placed at the end of the extraction system. In addition, the system can be equipped with a coolant device for rapid cooling of the resultant extract. As the unique properties of pressurized low-polarity water, the pressurized low-polarity water extraction has a disproportionately high boiling point for its mass, a high dielectric constant, and high polarity. As the temperature rises, there is a marked and systematic decrease in permittivity, an increase in the diffusion rate, and a decrease in the viscosity and surface tension. In consequence, more polar target materials with high solubilities in water at ambient conditions are extracted most efficiently at lower temperatures, whereas moderately polar and nonpolar targets require a less-polar medium, induced by elevated temperature.

Water changes dramatically when its temperature rises, because of the breakdown in its hydrogen-bonded structure with temperature. The high degree of association in the liquid causes its relative permittivity (more commonly called its dielectric constant) to be very high at ca. 80 under ambient conditions. But as the temperature rises, the hydrogen bonding breaks down and the dielectric constant falls, as shown in Figure 40.5. The most outstanding feature of this leaching agent is the easy manipulation of its dielectric constant (ε). In fact, this parameter can be changed within a wide range just by changing the temperature under moderate pressure. Thus, at ambient temperature and pressure, water has a dielectric constant of ca. 80, making it an extremely polar solvent. This parameter is drastically lowered by raising the temperature under moderate pressure. For example, subcritical water at 250°C and a pressure over 40 bar has $\varepsilon = 37$, which is similar to that of ethanol and allows for the leaching of low-polarity compounds. By 250°C, its dielectric constant has fallen so that it is equal to that for methanol (i.e., 33) at ambient temperature. Thus, between 100°C and 200°C, superheated water is behaving like a water–methanol mixture. Partly because of its fall in polarity with temperature, superheated water can dissolve organic compounds to some extent, especially if they are slightly polar or polarizable like aromatic compounds. Therefore, water can be used as extraction solvent to extract the polar, the moderately polar, and the nonpolar compounds by adjusting the extraction temperature from range of 50°C to 275°C.

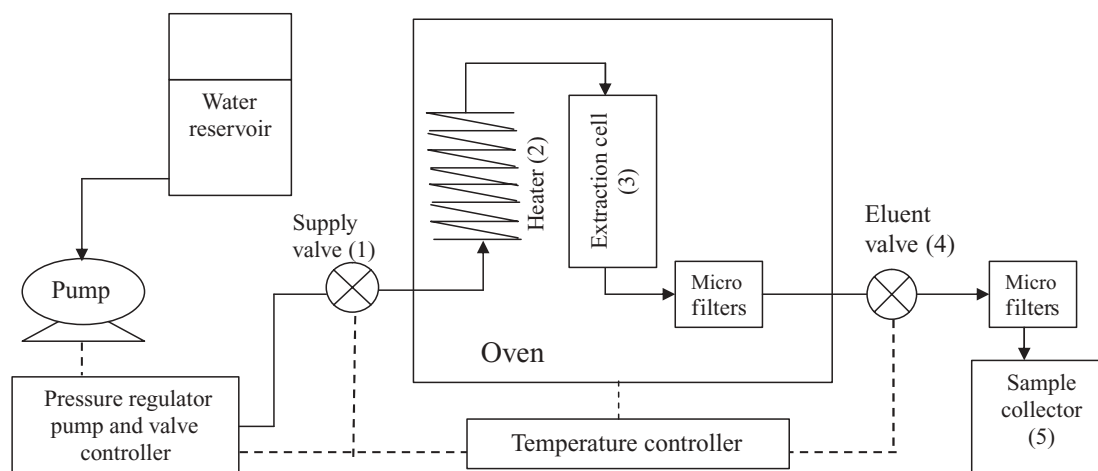
The solubility of an organic compound is often many orders of magnitude higher than its solubility in water at ambient temperature for two reasons. One is the polarity change and the other is that of a compound with low solubility at ambient temperature. Pressurized low-polarity water will have a high positive enthalpy of solution and thus a large increase in solubility with temperature. Because of the greater solubility of some


Figure 40.7. Diagram of pressurized low-polarity water extractor. The electrical connections are marked by dashed lines, while the path of subcritical water is shown by solid line with arrow. The high-pressured water passes through a supply vale (1) into a heating coil (2) and into an extraction cell (3). The microfilters are placed before and after an eluent valve (4). The extract is collected in a sample collector (5).

organic compounds in superheated water, this medium can be considered for the extraction and other processes, to replace conventional organic solvents. But some additional reactions of the compounds being processed may also occur, by hydrolysis, oxidation, etc.

Industrial Applications

Using pressurized low-polarity water provides a number of advantages over traditional extraction techniques (i.e., hydrodistillation, organic solvents, solid–liquid extraction). These are mainly shorter extraction times, higher quality of the extracts (mostly for essential oils), lower costs of the extracting agent, and an environmentally compatible technique. Since water is perhaps the most environmentally friendly solvent available in high purity and at low cost, it has been exploited for the extraction of avoparcin in animal tissue (Curren and King 2001), fungicides in agricultural commodities (Pawlowski and Poole 1998), fragrances from cloves (Rovio et al. 1999), antioxidative components from sage (Ollanketo et al. 2002), anthocyanins and total phenolics from dried red grape skin (Ju and Howard 2003), saponins from cow cockle seed (Güçlü-Üstündag et al. 2007), and other bioactive components from plant materials (Ong and Len 2003). Some additional successful applications of this technique are for the extraction of essential oils from various plant materials (Khajenoori et al. 2009, Mortazavi et al. 2010), extraction of sweet components from *Siraitia grosvernorii*, extraction of lactones from kava roots, extraction of antioxidant compounds from microalgae *S. platensis* (Ibáñez et al. 1999, Ibáñez et al. 2003, Herrero et al. 2004), extraction of *Ginkgo biloba*, and of biophenols from olive leaves (Japón-Lujána and Luque de Castro 2006).

The quality of the oil obtained is therefore better than that from steam distillation, as it contains more of the oxygenated

compounds and lower terpene content. The yield is also slightly higher than from steam distillation, in spite of the fact that all the terpenes are not extracted. This may be because, at the higher temperatures and under pressure, the plant material is more effectively penetrated. However, about twice the amount of water is required than for steam distillation. Energy costs are much less than for steam distillation. The energy required to heat a given mass of water from 30°C to 150°C under pressure is one-fifth of that needed to boil water at atmospheric pressure from 30°C. Furthermore, it is possible to recycle most (three-quarters) of the heat, whereas it is difficult to recycle heat in steam distillation. Thus, in spite of the fact that twice as much water is needed, only one-tenth of the energy of a steam distillation is required. Pressurized low-polarity water extraction has been suggested as a method to extract valuable health-promoting compounds from plant materials.

Molecular Distillation

Molecular distillation is a unit operation that is a peculiar case of evaporation, which happens under extremely low pressures and low temperatures and is used for the separation of constituents from mixtures by partial evaporation. It is based on the fact that the vapor is relatively richer in the component with the highest vapor pressure, that is, the more volatile component. Distillation is a process of heating a substance until the most volatile constituents change into the vapor phase, and then cooling the vapors to recover the constituents in liquid form by condensation. The main purpose of distillation is to separate a mixture into individual components by taking advantage of their different level of volatilities. Distillation is one of the main methods of extracting essential oils from plants. It can be carried out either as simple distillation or fractional distillation (rectification). In

simple distillation, the vapors are recovered by condensation. In rectification, successive vaporization and condensation are carried out simultaneously and a part of the condensed liquid, called the reflux, flows down the column countercurrent to the flow of vapors for isolating components from a mixture based on differences in boiling points. The percentage of each constituent in the vapor phase usually depends on its vapor pressure at a certain temperature. The principle of vacuum distillation may be applied to substances, such as oils, that would be damaged by overheating by the conventional method (Liu et al. 2008). Several new methods have been developed for the separation and recovery of minor components from vegetable oils such as palm oil (Rodríguez et al. 2007, Shi et al. 2007c).

Distillation and its companion processes, azeotropic and extractive distillations, are by far the most widely used separation processes for mixtures that can be vaporized. Vapors are generated from liquids or solids by heating and are then condensed into liquid products. However, many mixtures exhibit special states, known as azeotropes, at which the composition, temperature, and pressure of the liquid phase become equal to those of the vapor phase. Thus, further separation by conventional distillation is no longer possible. By adding a carefully selected other component as an entrainer to the mixture, it is often possible to "break" the azeotrope and thereby achieve the desired separation. In azeotropic distillation, a compound is added to form an azeotrope with at least one of the components of the mixture. That component can then be more readily separated from the mixture because of the increased difference between the volatilities of the components. Extractive distillation combines continuous fractional distillation with absorption. A relatively high-boiling solvent is used to selectively scrub one or more of the components from a mixture of components with similar vapor pressures. Distillation processes are also widely used for the separation of organic chemicals, usually at cryogenic temperatures.

Separation Processes in Distillation

When vacuum is applied, there are three major reduced pressure ranges that can be utilized for distillation: (a) distillation at moderate vacuum or equilibrium distillation, (b) unobstructed path distillation, and (c) molecular distillation. Distillation at moderate vacuum is characterized by the use of conventional distillation equipment as shown in Figure 40.8. Its lowest pressure limit is of the order of 1 Torr, that is, 1 mm Hg. Unobstructed path distillation is defined as distillation in which the path between the evaporator and the condenser is not blocked, in other words there is a free transfer of molecules (Eckles and Benz 1992). When the transfer distance is comparable with the mean free path of the vapor molecules, the distillation is known as molecular distillation.

Mean free path is defined as the average distance a molecule will travel in the vapor phase without colliding with another vapor molecule (Eckles et al. 1991). This implies that, in molecular distillation, the vapor molecules can reach the condenser without intermolecular collisions. A dynamic equilibrium can not be established between the vapor and the liquid. An individual

Figure 40.8. Molecular distillation system.

molecule that has evaporated will be able to travel any distance without a collision.

Molecular distillation occurs at low temperatures and, therefore, reduces the problem of thermal decomposition. High vacuum also eliminates oxidation that might otherwise occur in the presence of air. Unobstructed path and molecular distillations are often classified together as short-path or high-vacuum distillation. The difference is in the dimensions and operating conditions. Unobstructed path distillation is carried out at pressures as low as 10^{-2} Torr, while in molecular distillation pressures of 10^{-3} Torr, that is, a mTorr, are used. Another useful distinction between the methods of vacuum distillation can be made with reference to the way in which the vapor phase is formed: (a) Ebullition, (b) evaporative distillation, and (c) molecular distillation.

Ebullition is accompanied by the formation of bubbles when the saturated vapor pressure exceeds the pressure of the surrounding gas. The only limit to the rate of evaporation in this case is the rate at which heat can be transferred to the liquid. Evaporative distillation occurs when the pressure of the surrounding gas is higher than the vapor pressure of the liquid at a given temperature, so that bubbles are not formed. The rate of evaporation is controlled by the temperature of the liquid and the conditions above the liquid surface. In molecular distillation, the rate of evaporation is controlled by the rate at which the molecules escape from the free surface of the liquid and

condense on the condenser. The condenser should be in the immediate vicinity of the evaporating surface. When an appreciable number of collisions can occur in the vapor space, some of the molecules will return to the liquid. This leads to a decrease in the number of molecules that reach the condensation surface.

High-vacuum distillation may be used for certain classes of chemical compounds that decompose, polymerize, react, or are destroyed by conventional distillation methods. Low cost per pound and high throughput may be obtained on certain groups of compounds such as vitamins, epoxy resins, highly concentrated pure fatty acids, plasticizers, fatty acid nitrogen compounds, and a host of other heat-sensitive materials, which may require only deodorizing and decolorizing (Spychaj 1986, Batistella et al. 2002a,b, Cermak et al. 2007, Shao et al. 2007, Compton et al. 2008). High-vacuum distillation is a safe process to separate mixtures of organic or silicon compounds, most of which can not withstand prolonged heating without excessive structural change or decomposition. With short residence times and lower distilling temperatures, thermal hazards to the organic materials are greatly reduced. Purity of the distillate also depends on the film thickness. Controlling positive pressure and supply to the heated evaporator surface will usually provide a uniform film throughout the distillation. The absence of air molecules in the high-vacuum distillation column permits most of the distilling molecules to reach the condenser with relatively few molecules returning to the liquid film surface in the evaporator. Experimental results show a relationship between the molecular weight and distillation temperature for a broad range of different materials.

There are several basic design variations with short-path evaporators. These are the short-path falling film evaporator, the centrifugal molecular still, and the short-path, wiped-film evaporator. They operate at the lowest pressure of any system and are capable of high throughput per unit size, due to their continuous nature. They also offer the shortest thermal exposure to any process (Eckles and Benz 1992). Short-path, falling film evaporators can handle materials with viscosities up to 5000 cP, and the residence time, temperature, and pressure can be controlled. This is the simplest of the short-path stills, but more current designs use either centrifugal force or roller-wipers to spread the feed material on the evaporator surface. In the centrifugal molecular still, feed material is fed into the center of a heated spinning rotor. The material is evenly spread towards the edge and condensed in front of the rotor.

Molecular Distillation Applications

Molecular distillation, with its important characteristics of low pressure and low temperature, gives a high potential for this process in the separation, purification, and concentration of natural products, which usually consist of complex and thermally sensitive molecules. Especially under high vacuum for short operating times, while using no solvents, it avoids any toxicity problems. The effects of feed flow rate and distillation temperature on the extraction of minor components are related to the yield, purity, and rate of evaporation in terms of concentrations,

distribution coefficients, and relative volatilities. Molecular distillation is a valuable processing method that is often used to separate or purify high-boiling materials that decompose, oxidize, or polymerize at elevated temperatures. This process can be considered for industrial uses if both distillate and residue become high value-added products. Some molecular distillation processes are used in the production of biologically active substances such as vitamins, sterols, and antioxidants from natural oils and fats such as the extraction of vitamin A from fish liver and whale oil and carotenoid recovery from esterified palm oil (Batistella and Wolf Maciel 1998, Mutalib et al. 2003, Martins et al. 2006, Bettini 2007, Fregolente et al. 2007, Shi et al. 2007c), separation of mono and diglycerides in partially saponified fats (Holló and Kurucz 1968), and the refining of crude animal and vegetable oils (Martins et al. 2006, Behrenbruch and Dedigama 2007, Posada et al. 2007). For instance, a Malaysian company produces *Carotino*®, an edible red palm oil, using a process that involves a pretreatment of crude palm oil (i.e., degumming with phosphoric acid and treatment with bleaching earth) followed by deacidification and deodorization using molecular distillation (Ooi et al. 1996; Fig. 40.9). Recovery of special components used in the nutritional, pharmaceutical, and cosmetic areas from natural products by molecular distillation
Figure 40.9. Recovery system of water phase and oil phase in the orange juice industry (Bettini 2007).

processes have gained wide applications for products such as those derived from refined vegetable oils, e.g., deodorizer distillate of vegetable oils, palm oil for obtaining tocotrienols and tocopherols, rice oil for oryzanol recovery, monoglyceride concentration, carotenoid recovery from palm oil, heavy petroleum characterization, and herbicides (Barnicki et al. 1996, Sakiyama et al. 2001, Batistella et al. 2002a,b, Fregolente et al. 2005, Ito et al. 2006, Shi et al. 2007c). Recently, a new process of molecular distillation was developed for recovery of tocotrienols and tocopherols from rapeseed by a combination of acid-catalyzed methyl esterification and crystallization followed by fractional distillation of derived products and for the recovery of orange peel oil and essence products rich in aldehydes, esters, and other special volatile compounds (Lutisan et al. 2002, Jiang et al. 2006). An industrial production of a typical industrial fractional vacuum distillation plant is shown in Figure 40.10. In order to increase the yield and quality of the final products, the distiller is operated continuously.

Figure 40.10. The vacuum fractional molecular distillation column.

SUMMARY

One of the most important trends in the food industry today is the demand for "natural" foods and ingredients that are free from toxic chemical additives. The growing interest in natural foods has raised the demand for natural health-promoting products of nonsynthetic origin. High-value functional substances can be obtained from biological materials by various purification and separation methods from plant materials or by-products. Among the separation processes being used or developed are physical and chemical processes such as centrifugation, filtration, membrane separation, precipitation, chromatography, solvent extraction, supercritical fluid extraction, crystallization, evaporation, and distillation.

The separation problems presented by the production of soluble material have a number of aspects that influence the nature of the extraction technique chosen. An important factor is the stability of the extracted product. In the case of unstable products, a rapid separation process is necessary in order to avoid significant loss of products. Extraction with organic solvents by traditional methods is a well-established method for the selective separation of specific constituents from raw materials. The conventional procedures for preparing concentrated extracts are steam distillation or solvent extraction with an organic solvent. Extractants with a low boiling point, such as ethyl acetate, methanol, dichloromethane, etc., are traditionally used for isolating valuable constituents from such products as hops, spices, and oil seeds and also for removing or reducing the level of less-desirable accompanying substances (such as nicotine, caffeine).

But a very important step in the process is the complete removal of the solvents from extracts and its residue as they are in part toxicologically objectionable. In addition, organic solvents have a low selectivity. Extraction must be followed by removal of the solvent from the extract, for example by distillation. The challenges in the separation processes are to both meet food regulations and to conduct the separation effectively and economically. Many compounds in the concentrated extract will be thermally labile and prone to degradation if heated too vigorously. The removal of the solvent can pose serious problems since the residual level of the solvent must be minimized, but not at the expense of the degradation of the final extract. Public health, environment, and safety issues are the major concerns in the use of organic solvents in food processing. The possibility of solvent residues remaining in the final product has been a growing concern to consumers, thus warranting stringent environmental regulations. The extent of residual solvent levels and also the composition of the extraction solvents used in the food industry are well regulated within the existing laws and regulations. The solvents used for this purpose must meet the requirements of foodstuffs legislation, which can vary from country to country. In recent years, national and international bodies (such as the Food and Drug Administration, USA; the EC Codex Committee; and the FAO/WHO, Geneva) have increasingly emphasized the importance of complying with such criteria.

The demand for ultra-pure and high value-added products is redirecting the focus of the food and pharmaceutical industries

into seeking the development of new and clean technologies for their products. To solve these problems, some innovative emerging "green" processes such as supercritical CO_2 fluid extraction, membrane-based separations, molecular distillation, and pressurized low-polarity water extraction have provided excellent alternatives to the conventional organic solvent extraction methods. Extracts from natural sources are key elements in the manufacturing of health-promoting functional foods and ingredients. Especially such "green" separation processes and technologies are widely employed in the development of bioactive components for use as supplements for health-promoting foods.

Development of new and efficient separation processes will be based on more effectively exploiting differences in the actual physicochemical properties of food products. Liquid membrane extraction is one of the relatively new separation technologies that has significant potential for the selective separation and concentration of low-molecular weight chemicals used in food-processing industry.

Part 8
Food Safety and Food Allergens

41
Microbial Safety of Food and Food Products

J. A. Odumeru

PREFACE

Globally, food safety issues are of top priorities to the food industry, government food safety regulators, and consumers as a result of a significant increase in the number of foodborne disease cases and outbreaks reported worldwide in the twentieth century. These issues led to the proliferation of several food safety programs designed to reduce the incidence of foodborne illness. Although a number of producers and processors have implemented a variety of food safety programs, the occurrence of foodborne illness from emerging and existing pathogens remains a challenge to the food industry and food safety regulators. Food safety begins on the farm and continues through processing, transportation, and storage until the food is consumed. Food safety programs such as Good Manufacturing Practices (GMP),

Sanitation, Food Quality, and Safety Tests, and Hazard Analysis Critical Control Points (HACCP) are examples of food safety programs that are commonly used to control and monitor microbial contamination of food.

The three main categories of food safety concerns in the food industry include microbiological, chemical, and physical hazards. The microbiological hazards are those involving foodborne pathogens; chemical hazards include concerns related to antibiotics, pesticides, and herbicides; and physical hazards are those related to foreign objects in foods that can result in injury or illness when consumed with foods. Although this chapter addresses issues related to microbial hazards, food safety programs, which provide protection against these three types of hazards, especially during food processing, will be discussed. Foodborne organisms, sources of microbial contamination of foods and emerging pathogens, will be reviewed in relation to food safety issues.

INTRODUCTION

Food safety concerns are currently at an all-time high due to worldwide publicity about cases and outbreaks of foodborne illness. These concerns are now of top priority in the political and economic agendas of governments at various levels. One of the worst nightmares for food producers or processors is to have the name of their company show up in a news report as the source of a foodborne illness. Apart from the loss of consumer confidence and loss of sales, there are also legal aspects about which food companies must be concerned (Odumeru 2002). An estimated 76 million cases of foodborne illness per year occur in the United States, resulting in 325,000 hospitalizations and 5000 deaths (Mead et al. 1999). The economic impact of these illnesses is estimated at $5 billion or more. A number of food safety programs are currently in place in the food industry in an attempt to reduce the incidence of foodborne illness, which has been on

the rise in the last two decades (Maurice 1994). The increase in the incidence of foodborne disease has been attributed to a combination of factors. These include changes in food production and processing practices, changes in retail distribution, social changes including consumer preferences and eating habits, lack of experience of mass kitchen personnel, changes in population demographics, and increases in population mobility worldwide as a result of increases in international trade and travel (McMeekin and Olley 1995, Baird Parker 1994). Furthermore, advances in sciences in the area of analytical methods development has led to the availability of better detection methods for the diagnosis of foodborne illness and a subsequent increase in the number of cases reported. Other factors such as better reporting systems and increases in the occurrence of emerging pathogens have contributed to the increase in cases of foodborne diseases reported. Issues related to emerging pathogens will be discussed in a subsection of this chapter. A number of scientific tools are now available to the food industry and food safety regulators for implementing food safety programs designed to reduce the incidence of foodborne illness. These include the use of risk assessment of foods and food ingredients, to determine the risks associated with various types of foods under certain processing conditions; predictive modeling, which estimates the growth and survival of pathogens and spoilage organisms under specified conditions; and rapid methods for screening foods for quality and safety during and after production. This chapter will provide an overview of issues related to microbial safety of food and food products, food preservation technologies, emerging pathogens, food safety programs to control microbial contamination, and future perspectives on food safety.

SHELF LIFE OF FOODS AND FOOD INGREDIENTS AND FOOD SAFETY

The shelf life of a food product generally refers to the keeping quality of the food. An estimated 25% of the food supplies worldwide are lost as a result of spoilage; hence, it is economically beneficial to maintain the quality of food products at various stages of food production and storage. There are two categories of foods in relation to shelf life: shelf stable and perishable. Whether a particular food product is shelf stable or perishable depends on the intrinsic properties of the food (e.g., pH, water activity, and structure). Shelf-stable foods usually have low water activity, low pH, or a combination of both, while perishable foods tend to have high water activity and high pH. The structure or texture of the food is also an important factor in shelf stability. Extrinsic factors such as storage temperature, gaseous atmosphere, and relative humidity also determine the shelf stability of food products (McMeekin and Ross 1996). These intrinsic and extrinsic factors influence the survival and growth not only of spoilage organisms but also of pathogenic organisms in foods. Food spoilage occurs as a result of physical or chemical changes in the food or of the by-products of spoilage microorganisms growing in the food product. Pathogens present in low levels may not produce identifiable changes in the food;

hence, the presence of pathogens cannot be determined using noticeable changes in the food as an indicator.

Although shelf-stable foods are less likely to be implicated in foodborne illness than perishable foods, cross-contamination of shelf-stable or perishable foods by pathogens can be a source of foodborne illness. A number of preservation applications used in the food industry are designed to extend the shelf life of the food product by reducing microbial growth; however, pathogens that are able to survive or even grow under preservation techniques such as refrigeration can cause foodborne illness. Effective strategies for controlling the presence of spoilage and foodborne pathogens in foods should include elimination of sources of contamination combined with food preservation technologies such as drying, freezing, smoking, curing, fermenting, refrigeration (Baird-Parker 2000) and modified-atmosphere packaging (Farber 1991).

CATEGORIES OF FOODBORNE ORGANISMS

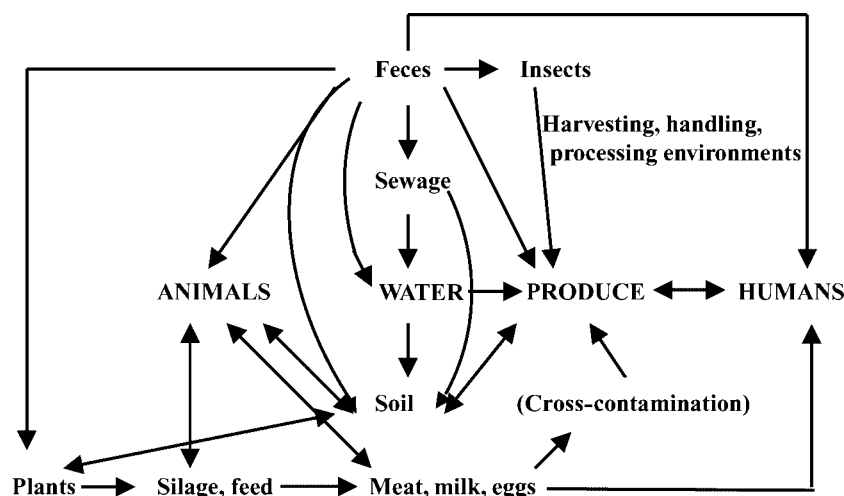
Microorganisms that can be transmitted to humans or animals through food are referred to as foodborne organisms. There are three main categories of foodborne organisms: spoilage, pathogenic, and beneficial. Spoilage organisms can grow and produce physical and chemical changes in foods, resulting in unacceptable flavor, odor, formation of slime, gas accumulation, release of liquid exudates or purge, and changes in consistency, color, and appearance. Also, extracellular or intracellular enzymes released by spoilage organisms can result in deterioration of food quality. Growth of microorganisms to high numbers is usually required before spoilage becomes noticeable. Hence, control of growth of spoilage organisms is required to impede microbial spoilage. The presence of foodborne pathogens in foods in low concentrations can render foods harmful to humans if consumed. Because pathogenic organisms at low levels may not produce noticeable changes in foods, consumers may not have advance warning signals of the danger associated with consumption of contaminated foods. "Beneficial" or "useful" organisms include microorganisms used in various food fermentation processes. These organisms are either naturally present in such foods or added to produce the desired by-product of fermentation. Various types of foods such as fruits and vegetables, pickles, dairy products, meats, sausages, cheeses, and yogurt are common types of fermented products involving the use of beneficial organisms. Beneficial organisms include organisms in the group of lactic acid bacteria, yeasts, and molds. Bacteria species from 10 genera are included in the group of lactic acid bacteria. These include *Lactococcus, Leuconostoc, Streptococcus, Lactobacillus, Pediococcus, Carnobacterium, Tetragenococcus, Aerococcus, Vagococcus,* and *Enterococcus.* The most important type of yeast used for fermentation of food and alcohol is *Saccharomyces cerevisiae.* This yeast is used for leavening bread and production of beer, wine, and liquors. It is also used for food flavor. Non-mycotoxin-producing molds from the genera *Penicillium* and *Aspergillus,* and some in the *Rhizopus* and *Mucor* genera, have been used for beneficial purposes in food preparation (Bibek 1996).


Figure 41.1. On-farm sources of microbial contamination of water and food products of plant and animal origin. (Adapted from Beuchat 1995.)

SOURCES OF FOODBORNE PATHOGENS

In order to determine and implement effective control measures for pathogens in foods, it is important to identify potential sources of contamination. Plants and animals are the main source of human food supply. The exterior and, in some cases, the interior of plants and animals harbor microorganisms from external sources such as soil, water, and air. These environmental sources contain a wide variety of microorganisms, some of which are pathogenic to man. Contamination of the food supply can occur at various stages of production, processing, transportation, and storage. For example, fruits and vegetables can be contaminated at the farm level as well as during harvesting, transportation, and processing. Potential sources of on-farm contamination of fruits and vegetables are summarized in Figure 41.1. Meats can be contaminated at the time of slaughter, processing, and storage. Microbial contamination can come from slaughtered animals, water, equipment, utensils, the slaughterhouse environment, and workers. Thus, intervention strategies to control microbial contamination of the food supply must be implemented at various stages of food production, processing, transportation, and storage, and also at the consumer end of food preparation.

FOODBORNE DISEASE CASES AND OUTBREAKS

Foodborne disease in a susceptible host can result from consumption of food or water contaminated with pathogenic organisms. A single or sporadic case of foodborne illness refers to an instance when an illness that is unrelated to other cases occurs as a result of consumption of contaminated food or water. An outbreak, on the other hand, refers to an incident in which two or more persons become ill after consuming the same food or water from the same source. The occurrence of a foodborne illness depends on a number of risk factors such as (1) type and number of pathogenic microorganisms in the food, (2) effect of food product formulation or processing on the viability of the pathogen, (3) storage conditions of the food that may promote contamination, growth, and survival of the pathogen, and (4) the susceptibility of the individual to foodborne illness. It is believed that the number of reported outbreaks represents only 10% of the real incidence of foodborne disease, even in countries with well-established surveillance systems (Baird-Parker 2000). Foodborne illness resulting from severe infections such as hemolytic uremic syndrome, botulism, and listeriosis often require hospitalization and are more likely to be reported, while self-limiting foodborne illness such as salmonellosis, campylobacteriosis, and *S. aureus* enterotoxin–related infections are less likely to be reported. It is believed that viral foodborne infections account for a large portion of cases of foodborne illness (Caul 2000). However, the extent of the problem on a global scale is difficult to assess as a result of lack of surveillance data in most parts of the world, coupled with the fact that most viral infections are self-limiting. Although viruses and bacteria-related infections account for the majority of foodborne diseases, certain groups of parasites and fungi are also etiologic agents of foodborne diseases.

FOODBORNE BACTERIAL INFECTIONS

Several types of foodborne bacterial pathogens are implicated in foodborne diseases. Examples of bacterial genera most commonly implicated in foodborne infections, onset and duration of the symptoms of the disease, types of foods that are likely to be contaminated by these groups of bacteria, and potential sources of contamination are summarized in Table 41.1. Bacterial pathogens including *Campylobacter, Salmonella, Listeria monocytogenes*, and verocytotoxigenic *E. coli* are the top causes of bacterial foodborne infections in westernized countries, based on the number of reported cases (Sharp and Reilly 2000). The

Table 41.1. Foodborne Bacterial Pathogens, Symptoms of Disease, Target Populations, and Potential Sources of Food Contamination

Organism	Symptoms	Onset	Duration	Target Population	Source	Suspect Foods
Bacillus cereus (*B. cereus*)	Two forms: 1. Diarrheal illness including abdominal cramps, nausea (vomiting rare) 2. Emetic illness including nausea and vomiting	Diarrheal: 6–15 hours Emetic: 30 minutes to 5 hours	Diarrheal: 12–24 hours Emetic: 6–24 hours	Everyone	Soil, Dust	Diarrheal: meat, milk, vegetables, fish, soups Emetic: rice products, potatoes, pasta, cheese products
Campylobacter jejuni	Diarrhea (may contain blood), fever, nausea, vomiting, abdominal pain, headache, muscle pain	2–5 days	2–10 days	Children under five, young adults 15–29	Cattle, chicken, birds, flies, stream, pond water	Raw chicken, turkey, raw milk, beef, shellfish, water
Clostridium botulinum	Fatigue, weakness, double vision, respiratory failure	18–36 hours, varies 4 hours to 8 days	Months	Everyone	Soil, sediment, intestinal tracts of fish and mammals	Canned foods, smoked and salted fish, chopped bottled garlic, sautéed onions, honey
Clostridium perfringens	Diarrhea, cramps, nausea (vomiting rare)	6–22 hours	Under 24 hours, may persist 1–2 weeks	Everyone, but young and elderly are most affected	Soil, feces	Meats, meat products, poultry, gravy
Escherichia coli (Traveller's diarrhea)	Watery diarrhea, abdominal cramps, low-grade fever, nausea, malaise	1–3 days	Days	Everyone	Water, Human sewage	Dairy products
E. coli O157:H7	Severe cramping, watery diarrhea becoming bloody, low-grade fever	12–60 hours	2–9 days to weeks	Children	Cattle, deer	Undercooked or raw hamburger, raw milk, unpasteurized apple cider
Listeria mono-cytogenes	Septicemia, maningoen cephalitis, spontaneous abortions, stillbirths, influenza-like symptoms	A few days to 6 weeks	Days to weeks	Pregnant woman, immunocom-promised persons, cancer and AIDS patients and those with chronic diseases, elderly, (fatality rate is as high as 70%)	Soil, improperly made silage	Raw milk, soft ripened cheeses, ice cream, raw vegetables, fermented raw meat, sausages, hot dogs, luncheon meats, raw and cooked poultry, raw and smoked fish

Organism	Symptoms	Onset	Duration	Susceptible population	Source	Foods
Salmonella	Nausea, chills, vomiting, cramps, fever, headache, diarrhea, dehydration	6–48 hours	1–4 days	Everyone, but more severe symptoms in infants, elderly, infirm, and AIDS patients	Water, soil, insects, animal feces, raw meat, raw poultry, raw seafood	Raw meats, poultry, eggs, milk, dairy products, fish, shrimp, frogs legs, yeast, coconut, sauces and salad dressings, cake mixes, cream-filled desserts and toppings, dried gelatin, peanut butter, cocoa, chocolate
Shigella	Abdominal pain, diarrhea, fever, vomiting, sometimes cramps, nausea	1–7 days	4–7 days	Infants, elderly, infirm, AIDS patients	N/A	Salads (Potato, tuna, shrimp, macaroni and chicken), raw vegetables, milk and dairy products, poultry
Staphylococcus aureus	Nausea, vomiting, cramps, diarrhea, prostrations	1–6 hours	1–2 days	Everyone	Air, dust, sewage, water, milk, food equipment, humans, animals, nasal passages and throat, hair, skin, boils	Meat and meat products, poultry and poultry products, salads, (egg, tuna, chicken, potato, macaroni) cream-filled pastries, cream pies, milk and dairy products
Vibrio cholera (Cholera)	Mild, watery diarrhea, abdominal cramps, nausea, vomiting, dehydration, shock	6 hours to 5 days	Days	Everyone, but especially those with immunocompromised systems, reduced gastric acidity, malnutrition	Raw shellfish, water, poor sanitation	Seafood, water

Table 41.2. The Incidence of the Four Most Frequent Foodborne Disease-Causing Pathogens in Canada and the United States

| Bacteria | Estimated Cases/Year (Based on Population Ratio) | |
	Canada	United States[a]
Campylobacter	110,000–700,000	1,100,000–7,000,000
Listeria	93–177	928–1767
Salmonella	69,600–384,000	696,000–3,840,000
Verotoxigenic *E. coli* (Including *E. coli* O157:H7)	1600–3200	16,000–32,000
Total	181,3000–1,087,400	1,812,900–10,873,800

[a]Adapted from Buzby and Roberts 1997.

number of reported cases of *Salmonella, Campylobacter*, and *E. coli* O157 increased from 2- to 40-fold between 1982 and 1994 (Sharp and Reilly 2000). The increase in the number of cases was attributed to heightened awareness of foodborne related illness, improved diagnostic methods, and improved reporting and surveillance procedures. *Campylobacter* is currently the leading cause of foodborne disease in the United States and Canada, followed by *Salmonella*-related infections. The numbers of estimated cases of foodborne illness per year in the United States and Canada countries are listed in Table 41.2. Although the number of *Listeria monocytogenes*–related infections is considerably lower than those of other pathogens, foodborne infections caused by this organism are characterized by a high case mortality ratio, especially in certain high risk groups such as the elderly, the young, immunocompromised individuals, and pregnant women. Infections caused by *E. coli* O157:H7 often result in a high morbidity and mortality rate. For example, complications such as hemolytic uremic syndrome can result in kidney failure and death (Riley et al. 1983, Karmali 1989). Sources of bacterial infections are not limited to contaminated foods; contaminated water and person-to-person transmission have also been implicated. For example, in a waterborne outbreak of *E. coli* 0157:H7 in Walkerton, Ontario, 1700 cases and seven deaths were reported. This led to changes in the Ontario Drinking Water Regulations to include strict water treatment procedures and zero tolerance for the presence of coliforms and *E. coli* in drinking water. Current food safety programs in the food industry must now document the use of pathogen-free water in food production and processing facilities.

CAMPYLOBACTER ENTERITIS

Campylobacter jejuni and *C. coli* are the species of *Campylobacter* implicated in most *Campylobacter* enteritis infections. Other species of *Campylobacter* such as *C. lari* and *C. upsaleusis* may also cause *Campylobacter* enteritis. Symptoms of *Campylobacter* infection in humans are watery and/or bloody diarrhea, abdominal pain, fever, and general malaise. The disease is usually self-limiting, and antibiotics are required only when complications occur. It is estimated that *Campylobacter* enteri-

tis accounts for 10% of cases of foodborne illness, and death is rarely reported. Most cases of this disease are sporadic, and foods of animal origin, particularly poultry, are largely responsible for most infections. Contaminated fruits and vegetables have also been implicated in *Campylobacter* enteritis cases.

SALMONELLOSIS

Salmonellosis infection ranks second in incidence to *Campylobacter* enteritis. This organism is ubiquitous (present everywhere) in the environment, especially in the feces of most food-producing animals; hence, a variety of foods are readily contaminated by this organism. *Salmonella* are present in animals without causing apparent illness. However, certain serotypes of *Salmonella* such as *S. enteritidis* can penetrate poultry reproductive organs, resulting in contamination of egg content and posing a health risk to consumers. Salmonellosis symptoms include watery diarrhea, abdominal pain, nausea, fever, headache, and occasional constipation. Hospitalization may be required in cases of severe infections. Foods that can become contaminated with *Salmonella* include meat, raw milk, poultry, eggs, dairy products, and other types of foods that can become contaminated with fecal material. An increase in the number of cases of Salmonellosis linked to consumption of contaminated fruits and vegetables such as bean sprouts, raw tomatoes, melons, and cantaloupes has been reported. In addition to fecal contamination, cross-contamination of foods by *Salmonella* during food preparation can be a source of foodborne illness.

LISTERIOSIS

Listeriosis is caused by *Listeria monocytogenes*. The ubiquitous nature of this organism contributes to the widespread incidence of the organism in foods. It is psychrotrophic in nature and is able to grow at refrigeration temperatures. Hence, this organism is of concern in refrigerated foods with extended shelf life. Listeriosis infections often result in septicemia and/or meningitis. The case mortality ratio for Listeriosis infections is much higher than those of *Salmonella*, *Campylobacter,* and *E. coli* 0157:H7 infections. An estimated 500 deaths associated with Listeriosis

are reported annually in the United States. Individuals most susceptible to Listeriosis include the elderly, the young, immunocompromised patients, and pregnant woman. A wide variety of foods including processed meats, milk and dairy products, fruits, and vegetables have been implicated in a number of Listerioses outbreaks. In 1999, a multistate outbreak involving 1000 cases of Listeriosis in the United States was linked to consumption of contaminated hot dogs and delicatessen meats, resulting in a recall of 35 million pounds of these food products (MMWR 1999).

VEROTOXIGENIC *ESCHERICHIA COLI* (VTEC) INFECTIONS

Verotoxigenic *Escherichia coli* (VTEC) belonging to the O157 serogroup is the most common VTEC serogroup implicated in foodborne disease outbreaks. This organism was first recognized as a cause of hemorrhagic colitis in 1982. VTEC O157 and serogroups O5, O26, and O111 are of high prevalence in feces of healthy cattle. Thus, foods of animal origin such as meat, milk, and dairy products can be contaminated with these organisms. Other types of foods such as salads, vegetables, fruits, sandwiches, and cooked meat can be contaminated during preparation. Contaminated water can also be a source of infection by this organism. The majority of food- and waterborne outbreaks had links with contamination of fecal origin. Infection by VTEC can result in hemorrhagic colitis (HC) and hemolytic uremic syndrome (HUS), abdominal pain, and watery diarrhea (bloody or nonbloody). The HC symptoms may lead to complications of the HUS and subsequent renal failure. Although HUS can occur in any age group, children are more susceptible (Karmali 1989). In adults, 50% of thrombocytopenic purpura (TP) cases are caused by HUS.

Other bacterial foodborne infections can occur as a result of ingestion of food contaminated with *Staphylococcus aureus* toxin, *Clostridium perfringens, Clostridium botulinum* toxin, S*higella* spp., *Yersinia enterocolitica, Brucella* spp., *Vibrio cholera, Vibrio paraheamolylicus*, and *Bacillus cereus* enterotoxin.

FOODBORNE PARASITE INFECTIONS

Foodborne parasite infections are caused by certain groups of protozoa. It is believed that foodborne infections related to parasites are underreported by an estimated factor of 10 or more (Casemore 1991), and the etiological agent of foodborne outbreaks is identified in less than 50% of the cases (Bean et al. 1990, Cliver 1987). Parasites commonly associated with foodborne disease and possible food and water sources are listed in Table 41.3.

Cryptosporidium parvum is the species of *Cryptosporidium* associated with infection in humans (Current and Blagburn 1990). It is a common cause of gastrointestinal infections in immunocompromised individuals and is an opportunistic pathogen associated with infections in patients with acquired immune deficiency syndrome (AIDS), but it affects healthy people as well. Although drinking water contaminated with human or animal feces is the usual source of transmission of this organ-

Table 41.3. Foodborne Parasites, Fungi, and Viruses Associated with Food- or Waterborne Illness

Pathogen	Sources of Pathogen or Toxin
Parasites	
Cryptosporidium	Contaminated surface water or foods in contact with contaminated water
Cyclospora	Raspberry, mesculun lettuce, and basil
Sarcocystis	Raw or undercooked meat
Toxoplasma	Raw or undercooked meat
Giardia	Contaminated surface water
Fungi	
Penicillium	Mycotoxins in apple juice, walnuts, corn and cereals
Aspergillus	Mycotoxins in groundnuts, corn, figs and tree nuts
Fusarium	Mycotoxins in cereals, corn, wheat and barley
Viruses	
Hepatitis A and E	Contaminated water, fruits and vegetables, raw shellfish, raw oysters
Norwalk/Norwalk–like viruses	Variety of foods and water
Calcivirus	Water and contaminated foods
Astrovirus	Water and contaminated foods

ism to humans, epidemiological links between the consumption of contaminated foods such as raw sausage, offal, and raw milk and cryptosporidiosis have been reported (Casemore 1990, Casemore et al. 1986). The largest outbreak of waterborne cryptosporidiosis was reported in Milwaukee, Wisconsin, with 403,000 persons ill. Reported outbreaks in most countries are associated with contaminated drinking water or contaminated swimming pools.

Cyclospora is an emerging pathogen, which causes diarrheal infections in humans. The first reported outbreak of *Cyclospora* infection occurred in 20 US states and two provinces in Canada, Ontario and Quebec, during the months of May and June, 1996, and April and May, 1997. Consumption of contaminated imported raspberries was implicated in many of these outbreaks (Herwaldt and Ackers 1996, Herwaldt and Beach 1997). Contaminated mesclun lettuce and basil have also been linked to *Cyclospora* outbreaks (MMWR 1997).

Sarcocystis is another coccidian parasite, which is prevalent in livestock. Human infection occurs as a result of ingestion of raw or undercooked meat containing mature sarcocysts (Tenter 1995).

Toxoplasma gondii is an intracellular parasite, which is prevalent in man and animals (Fayer 1981). Ingestion of raw or undercooked meat from livestock and game animals is often implicated in human toxoplasmosis infections. Another parasite commonly implicated in food and waterborne illness is *Giardia*.

Outbreaks of food and waterborne illness have been reported in the United States and the United Kingdom (Craun 1990, Porter et al. 1990). Infection with this parasite is associated with unsanitary conditions, and contaminated water is the most common source of infection.

FOODBORNE FUNGI

Fungi most commonly associated with foodborne intoxications are *Penicillium, Aspergillus,* and *Fusarium*. The types of foods that may contain mycotoxin contamination are listed in Table 41.3. A foodborne fungi outbreak associated with consumption of corn contaminated with *Aspergillus flavus* was reported in India. The outbreak involved 1000 cases and 100 deaths (Krishnamachari et al. 1975). Mold growth can occur in foods stored under high temperature or humidity, resulting in the production of mycotoxin, which can be harmful to humans.

FOODBORNE VIRUS INFECTION

Viruses from human fecal origin can result in illness if ingested with food or water. Food or waterborne viruses commonly associated with human illness are listed in Table 41.3. Viral gastroenteritis is caused by Norwalk-like viruses and in some cases by the calicivirus and astrovirus groups. The symptoms often include acute but short self-limiting episode of diarrhea and vomiting. The viruses can be transmitted from person to person via contaminated utensils and foods. Foodborne viral hepatitis in humans is caused by the hepatitis A or hepatitis E virus. The onset of hepatitis may be preceded by anorexia, fever, fatigue, nausea, and vomiting. Infected individuals shed the organism in feces, which if allowed to contaminate food or water, can result in person-to-person transmission (Caul 2000).

EMERGING PATHOGENS AND FOOD SAFETY

Emerging infectious diseases have increased in the last two decades and are likely to increase in the future. Hence, the characteristics of the etiologic agents of these diseases must be considered when designing control measures to ensure food safety. There are two types of emergence: true emergence and reemergence. A true emergence involves the occurrence of microbial agent not previously identified as a public health threat. A reemergence involves the occurrence of a microbial agent causing disease in a new way not previously reported or the reemergence of a human disease after a decline in incidence. Emergence may be due to the introduction of a new agent, to recognition of an existing disease that was not previously detected, or to environmental pressures resulting in occurrence of a pathogen that can cause human disease. For example, the occurrence of enterohemorrhagic *E. coli* O157:H7 as a pathogen in 1982 is believed to be due to introduction of a new agent. The organism was involved in two outbreaks that year in the United States, and these outbreaks were associated with consumption of undercooked hamburgers from a fast-food restaurant chain. Several countries worldwide have reported outbreaks of infection caused

Table 41.4. Emerging Pathogens and Suspected Causes of Emergence

Pathogens	Cause of Emergence
Salmonella DT104	Resistance to antibiotics
E. coli O157:H7	Development of a new pathogen
Cyclospora cayetanensis	Development of a new pathogen
Cryptosporidium parvum	Development of a new watershed areas
Hepatitis E virus	Newly recognized
Norwalk Virus	Increased recognition
Aeromonas Spp.	Immunosuppression and improved detection
C. jejuni	Increased recognition, consumption of uncooked poultry
L. monocytogenes	Increased awareness
Helicobacter pylori	Increased recognition
Vibrio vulnificus	Increased recognition

by this organism. The appearance of *Salmonella typhimurium* phage type 104 is another example of a new agent. Increases in the use of antibiotics in humans and animals may have provided the environmental pressures resulting in the occurrence of *Salmonella typhimurium* phage type 104 with multiresistance to five antibiotics: ampicillin, chloramphenicol, streptomycin, sulphonamides, and tetracycline. This multiresistant characteristic leaves little choice of antibiotics for treatment of disease caused by this organism. The occurrence of *Listeria monocytogenes* as a foodborne agent is an example of reemergence. The organism is a well-known infectious agent; however, its role as a foodborne organism was not detected until the early 1980s. Examples of emerging foodborne pathogens and possible causes of emergence are provided in Table 41.4. The challenge posed by the appearance of emerging pathogens is that these organisms may not always behave as traditional pathogens. Therefore, new control measures to ensure that foods are free of these pathogens may be required.

CONTROL MEASURES FOR MICROBIAL CONTAMINANTS

A combination of factors is normally responsible for occurrence of an incident of foodborne illness. The pathogen must first reach the food involved; the organism must survive until food is ingested; in many cases, the organism must multiply to an infectious level or produce toxins; and lastly, the host must be susceptible to the level of organisms ingested with the food. Control measures to ensure food safety include (1) prevention of contamination of foods by pathogenic organisms (2) inhibition of growth or elimination of pathogens in foods and food products. The first stage of control measures is to prevent contamination of food animals and plants during the production stage. Production practices such as the use of manure and other organic fertilizer materials can provide the vehicle for contamination of food

crops; hence, it is important to ensure that this type of fertilizer is pathogen-free prior to use. The second stage of control measure is to prevent contamination and growth of pathogenic organisms during harvesting and transportation of food products. It is generally believed that control of microbial contamination early in production is more effective than control measures applied at a later stage of production. However, in cases when the presence of pathogens cannot be eliminated during the production stage, processing procedures that are designed to control the presence of pathogens must be implemented. A combination of intrinsic factors, (i.e., factors associated with the properties of the food) and extrinsic factors (i.e., factors associated with external conditions) is often used during processing and storage to control microbial growth or survival in foods (Bibek 1996). Intrinsic factors such as the pH, water activity, and food components can promote or inhibit microbial growth or survival. These properties can be used in combination with extrinsic factors such as heat, preservatives, irradiation, and storage conditions (e.g., refrigeration, relative humidity, and gaseous atmosphere).

Currently, there are several food preservation technologies available for controlling microbial growth and survival. The most commonly used technologies for controlling microbial growth include application of low temperatures such as refrigeration or freezing, reduction of water activity of the food by drying, curing with salt or increased sugar level, pH reduction by acidification or fermentation, use of food preservatives, and modified atmosphere techniques. Other preservation technologies designed to inactivate foodborne organism include heat treatment such as sterilization, cooking, retorting, pasteurization, irradiation, and the use of hydrostatic pressure and pulse light. Also, use of packaging materials and adequate sanitation of the food production or processing environment can be used to limit entry of microorganisms into the food product and prevent recontamination of processed foods (Gould 1989, Hall 1997). The use of a combination of preservation techniques, often referred to as the hurdle concept, can be very effective in controlling microbial growth. A combination of suboptimal levels of the growth-limiting factors can be very useful where higher levels of one of the factors can be detrimental to the quality of the product. The most important hurdles used in food preservation include high or low temperature, water activity (aw), redox potential (Eh), acidity (pH), preservatives such as sulfite, nitrite, and sorbate, and the use of competing microorganisms such as lactic acid bacteria. The application of an appropriate combination of these hurdles can improve the microbial stability, sensory and nutritional qualities, and safety of the foods.

FOOD SAFETY PROGRAMS

Traditional approaches to controlling the safety and quality of foods involve inspection of foods after production or processing for compliance with general hygienic practice, and where appropriate, foods are sampled for laboratory testing. This approach does not ensure food safety since reliance on visual inspection and testing of finished products cannot guarantee the absence of harmful pathogens in food. A more effective food safety control program, called the hazard analysis critical control point

(HACCP) program, was introduced to the food industry in the early 1970s, and various food safety regulations and trade bodies worldwide endorsed its use as an effective and rational approach to assurance of food safety. HACCP is a systematic approach to hazard identification, assessment, and control. The benefits of the HACCP approach to ensuring food safety include the following:

- The food industry has a better proactive tool for ensuring the safety of foods produced.
- Potential food safety problems can be detected early.
- Food inspectors can focus more on verifying plant controls.
- More effective use is made of resources by directing attention to where the need is greatest.
- A significant reduction in the cost of end product testing is achieved.

There are seven key principles of HACCP. Principle No. 1 includes hazard analysis to identify the microbiological, chemical, and physical hazards of public health concern. Raw materials processing procedures, including packaging and storage, are assessed for microbiological hazards. The second principle is to determine the procedures or points in the food operation where hazards can be controlled effectively. These are called the critical control points (CCPs). The third principle includes the establishment of critical limits that separate acceptable from nonacceptable limits. The fourth principle involves the development of a system to monitor the CCPs so that the limits are not exceeded. The fifth principle is to determine what corrective actions to take when the CCPs are exceeded. The sixth principle includes the establishment of procedures for verifying that the HACCP program is working as expected. The seventh principle involves the documentation procedures and records for all aspects of these six principles. These HACCP principles have received worldwide recognition, by governments and the food industry. Many industrial organizations have adopted this food safety program as a means of controlling food safety hazards.

One of the most successful food safety programs at the consumer level is the FightBac program developed by the Partnership for Food Safety Education (PFSE), formed in 1997. This nonprofit organization provides education on safe handling of food to the public. The key features of the information on safe handling of food in the FightBac program are summarized in Table 41.5. Further information on this program can be found in the FightBac website (www.fightbac.org). Implementation of these safe food-handling procedures by consumers can prevent the occurrence of foodborne illness.

FUTURE PERSPECTIVES ON FOOD SAFETY

Foodborne disease is preventable, provided control measures to prevent contamination of the food supply are implemented at various stages of the food chain, from the farm to the point of consumption. On-farm food safety programs include control measures for preventing contamination of plants, animals, and plant and animal products that are produced for human consumption. Implementation of effective environmental sanitation, good

Table 41.5. Four Simple Steps for Consumers to Ensure Food Safety (FightBac!™)

Clean: Wash hands and surfaces often
- Wash your cutting boards, dishes, utensils, and counter tops with hot soapy water after preparing each food item and before you go onto the next food
- Use plastic or other nonporous cutting boards
- Consider using paper towels to clean up kitchen surfaces

Separate: Don't cross-contaminate
- This is especially true when handling raw meat, poultry, and seafood
- Never place cooked food on a plate that previously held raw meat, poultry, or seafood

Cook: Cook to proper temperatures
- Use a clean thermometer that measures the internal temperatures of cooked foods to make sure meat, poultry, casseroles, and other foods are cooked all the way through
- Cook roasts and steaks to at least 145°F. Whole poultry should be cooked to 180°F for doneness
- Cook ground beef, where bacteria can spread during processing, to at least 160°F
- Don't use recipes in which eggs remain raw or only partially cooked

Chill: Refrigerate promptly
- Refrigerate or freeze perishables, prepared foods, and leftovers within 2 hours or sooner
- Never defrost at room temperatures. Thaw food in the refrigerator, under cold running water, or in the microwave. Marine foods in the refrigerator
- Divide large amounts of leftovers into small, shallow containers for quick cooling in the refrigerator

manufacturing practices (GMPs) and hazard analysis critical control points (HACCP) programs are key control measures for microbial, chemical, and physical hazards, not only at the farm level, but also during food processing, transportation, storage, and final preparation of foods prior to consumption. Furthermore, education and training of producers, processors, retailers, restaurant personnel, and consumers are important in the implementation of control measures to ensure the safety of foods consumed. Also, adequate inspection of food processing facilities and operations is very important to ensure that sanitation, GMP and HACCP protocols are being followed on a consistent basis. In order to implement a HACCP program successfully, the management of food operations must be committed to the program, by being aware of the benefits the program offers, and be prepared to invest time and money into the program. The use of microbiological testing as a verification tool for food safety programs including HACCP is important in providing evidence that indeed the control measures in place are effective. Finished product testing alone must not be relied on as means of ensuring food safety. The application of rapid methods for microbiological tests provides a useful tool for ensuring production of a safe food product at various points in the HACCP implementation. Microbiological tests can be performed for (1) the raw materials required for processing, (2) monitoring critical control points, and (3) HACCP verification. The reliance on testing of finished food products alone is a thing of the past. The challenge to food microbiologists now is to develop on-line food safety testing tools that can be used during food production. The limitation of current rapid tests for foodborne pathogens is that they require 24 hours or more to complete because of the requirement for amplification of pathogen numbers to detectable levels. The ability to detect pathogens at very low levels within seconds, minutes, or in less than 24 hours is an important future development for food microbiologists.

The likelihood of future increases in the incidence of foodborne illness is high as a result of increases in the number of susceptible aging populations, the treatment of disease with immunosuppressing drugs, and increases in the availability of ready-to-eat foods requiring no further processing prior to consumption. Unless steps are taken to implement food safety programs, which can reduce microbial contamination of foods at all levels of food production, processing, and retailing, and to educate restaurant personnel and consumers about the safe handling of foods, outbreaks of foodborne illness will continue to occur.

Food Allergens

J. I. Boye, A. O. Danquah, Cin Lam Thang, and X. Zhao

Abstract: The management of allergens along the food value chain and the diagnosis of food allergic diseases continue to pose serious challenges to the food industry as well as health care professionals. Of the over 170 foods known to provoke allergic reactions, nine foods (and their derived products) are today considered to be major allergens accounting for over 90% of all food allergic reactions. These priority allergens include milk, eggs, soya beans, peanuts, tree nuts (e.g. almonds, walnuts, pecans, cashews, Brazil nuts, hazel nuts, pistachios, pine nuts, macadamia nuts, chestnuts and hickory nuts), seafood such as fish (i.e. both saltwater and freshwater

finfish), crustaceans (e.g. shrimp, prawns, crab, lobster and crayfish) and molluscs (e.g. snails, oysters, clams, squid, octopus and cuttlefish), gluten-containing cereals (i.e. wheat, rye, barley and their hybridised strains and products), sesame and mustard. Symptoms of food allergic reactions and the threshold dose required to provoke allergic reaction markedly vary among sensitised individuals. Food production practices, processing conditions and matrix effects can also modify the molecular structure of food allergens and their potential immunogenic properties which can make allergens difficult to detect even when present in foods. This chapter provides an overview of the different types of food hypersensitivities including a distinction between food allergies and food intolerance, the properties of the nine priority food allergens, current approaches for the management of food allergens and a summary of some of the current methods used in food allergen detection.

INTRODUCTION

Humans require food to survive. In addition to basic nutrition, food consumption provides a sense of satisfaction and culinary pleasure and also serves as a source of social entertainment. However, for a small percentage of the population, consumption of certain foods even in small quantities can result in life-threatening allergic reactions. Approximately 4–8% of young children and 2–4% of adults in developed countries suffer from food allergies (Kanny et al. 2001, Munoz-Furlong et al. 2004, Sampson 2004, Sicherer et al. 2004, Breiteneder and Mills 2005). Although over 170 foods are known to cause food allergies, nine foods (and their derived products) are today considered to be major allergens accounting for over 90% of all food allergic reactions. These priority allergens include milk, eggs, soya beans, peanuts, tree nuts (e.g. almonds, walnuts, pecans, cashews, Brazil nuts, hazel nuts, pistachios, pine nuts, macadamia nuts, chestnuts and hickory nuts), seafood such as fish (i.e. both saltwater and freshwater finfish), crustacea (e.g. shrimp, prawns, crab, lobster and crayfish) and molluscs (e.g. snails, oysters, clams, squid, octopus and cuttlefish), gluten-containing cereals (i.e. wheat, rye, barley and their hybridised strains and products), sesame and mustard.

Food allergy is thus emerging as a growing public health problem. Unfortunately, the management of food allergens along the food value chain and the diagnosis of food allergic diseases continue to pose a challenge to the food industry as well as health care professionals. The factors responsible for this are varied. Multiple foods can induce food allergic reactions, and the threshold dose required to provoke allergic reaction markedly varies for different patients; thus, small quantities of foods can cause severe reactions in sensitised individuals, whereas other sensitised individuals can tolerate quantities of the allergen that are orders of magnitude higher. Additionally, symptoms of food allergies vary tremendously among sensitised individuals, and food production practices, processing conditions and matrix effects can alter the molecular structure of food allergens and their potential immunogenic properties and detection. In this chapter, we will provide an overview of the different types of food hypersensitivities, including a distinction between food allergies and food intolerance, the properties of the nine priority food allergens, current approaches for the management of food allergens and a summary of some of the current methods used for food allergen detection.

FOOD HYPERSENSITIVITY

Food Allergy

Food allergy is an immunological reaction resulting from the ingestion, inhalation or atopic contact of food. Immunological reactions can be mediated by IgE antibodies or other immune cells such as T cells. Some workers define food allergy specifically as being those immunological responses mediated by immunoglobulin E (IgE) antibodies, whereas others use the broader definition of immunological response, which include T-cell mediated responses as well. In this chapter, the latter definition will be used.

In general, any protein-containing food can elicit an allergic response in sensitised individuals. Allergenic proteins in foods may be enzymes, enzyme inhibitors, structural proteins or binding proteins with varied biological functions (Stewart and Thompson 1996, Valenta et al. 1999, Chapman et al. 2000, Martin and Chapman 2001). The pathogenesis of food allergy begins with a sensitisation phase during which time the body recognises one or more proteins in a particular food source as a foreign invader and begins to mount an immune-defensive response. Subsequent consumption of the offending food can result in an allergic response that may manifest in one of two forms, that is, immediate or delayed response as described below.

Immediate Hypersensitivity Reactions

Immediate hypersensitivity reactions are mediated by a specific class of antibodies known as IgE. Symptoms of an IgE-mediated food allergy develop within a few minutes to a few hours after an individual has ingested the offending food (Taylor 2000). During the sensitisation phase, the body produces IgE antibodies, which recognise allergenic fragments from the offending food. After production, IgE antibodies circulate in the blood and bind to basophiles and to the surface of mast cells (Taylor 2000). Mast cells and basophiles contain granules packed with potent inflammatory mediators such as histamine, cytokines and other chemotactic factors. When an allergic person encounters an allergen to which the person has previously produced IgE antibodies, the allergen combines with the IgE antibody on the surface of the mast cells and basophiles. This triggers a complex series of reactions that result in the release of histamine and other chemical mediators (prostaglandin D2, tryptase, heparin, etc.) from the granules inside the mast cells and basophiles (Taylor and Lehrer 1996, Lu et al. 2007). Histamine as well as the other chemical mediators has been shown to be the agents responsible for producing symptoms of allergy. The release of some of these mediators occurs rapidly, within 5 minutes after the interaction between the allergen and the IgE antibody (Taylor 2000). Once released, these compounds enter the blood stream

and bind to 'receptors' on other cells in the body, causing typical allergic symptoms.

The severity of an allergic reaction depends on how sensitised the person is and the amount of the allergenic component ingested. Histamine released from mast cells is usually complete within 30 minutes after the allergen–IgE antibody interaction. The release of mediators (other than histamine) is slower and their effects are more prolonged. Allergic reactions may, thus, sometimes occur in two phases. The first stage or first symptoms disappear on their own or with medication only to recur in 4–6 hours. Reactions may range from mild to severe life-threatening conditions, and may manifest as gastrointestinal disorders (nausea, vomiting, diarrhoea and abdominal cramping), or involve the skin, leading to urticaria or hives, dermatitis, eczema, angioderma, pruritis or itching. It may also involve the respiratory tract, in which case the individual may suffer from rhinitis, asthma or laryngeal oedema. Systemic anaphylaxis represents the most dramatic and potentially catastrophic manifestation of immediate hypersensitivity. Virtually, every organ in the body can be affected, although reactions involving the pulmonary, circulatory, cutaneous, neurological and gastrointestinal tract are the most common (Anderson 1986).

About 1–2% of the total population are affected by IgE-mediated food allergies (Chafen et al. 2010). The most vulnerable group are infants and young children, with 5–8% infants under 3 years being affected (Sampson and McCaskill 1985, Motala and Lockey 2004, Sicherer 2010). More than 170 different foods have been implicated in immediate hypersensitivity reactions (Hefle et al. 1996, Taylor 2000).

Delayed Hypersensitivity Reactions

Unlike the immediate hypersensitivity reactions described above, symptoms associated with delayed hypersensitivity induced by T-cells may appear after several hours to even days following consumption of the offending food. Delayed allergic reactions to food are relatively more difficult to identify unless the suspected food is eliminated from the diet for at least several weeks and then slowly reintroduced followed by monitoring for the onset of any physical, emotional or mental changes (Anderson 1986). These reactions are mediated by tissue-bound immune cells, and the acuteness of the reaction may be less than that of the immediate reactions (Taylor 2000). An example of delayed hypersensitivity reaction to food is celiac disease (CD), which is described in greater detail below.

Food Intolerance

Food intolerances are abnormal reactions to food or food components that do not involve the immune system (Breneman 1987). They are generally less severe, shorter in duration and more localised than immunological reactions. Food intolerances are the most common types of food sensitivities and specific examples include the metabolic food disorders and anaphylactoid responses described below.

Metabolic Food Disorders

Metabolic food disorders arise from inherited genetic deficiencies that reduce the capacity of afflicted individuals to efficiently metabolise food components. One such example is lactose intolerance, which is caused by an inherited deficiency of the digestive enzyme lactase, which hydrolyses lactose in milk and milk products into galactose and glucose for further processing within the body. As a result, the undigested lactose cannot be absorbed by the small intestine and passes into the colon where bacteria metabolise it into carbon dioxide (CO_2) and water (H_2O), leading to bloating, abdominal cramping and frothy diarrhoea (Taylor 2000).

Another example is phenylketonuria, a metabolic disorder in which afflicted individuals are deficient in the hepatic enzyme phenylalanine hydroxylase, which metabolises phenylalanine into tyrosine. Thus, phenylalanine and phenylpyruvate accumulate in the body, and if left untreated, it could affect the central nervous system and cause mental retardation and/or brain damage in infants and children.

A third example of food intolerance due to a genetic deficiency is favism, where individuals are intolerant to fava beans or the pollen from the *Vicia faba* plant. Persons with this intolerance have an inherited deficiency of the erythrocyte glucose-6-phosphate dehydrogenase (G6PDH) enzyme, which is essential to protect erythrocyte membranes against oxidative damage (Taylor 2000). This deficiency is crucial as several endogenous oxidants present in broad beans, for example, vicine and convicine, are capable of damaging erythrocyte membranes in G6PDH-deficient individuals, resulting in acute haemolytic anaemia with pallor, fatigue, dyspnoea, nausea, abdominal and/or back pain, fever and chills. It may even lead to more serious symptoms such as haemoglobinuria, jaundice and renal failure, but these situations are rare. Symptoms occur quite rapidly, usually within 5–24 hours following consumption of fava beans.

Anaphylactoid Responses

Anaphylactoid responses are due to the non-immunologic release of chemical mediators, such as histamine, from mast cells (Sampson et al. 1992). The specific substances that cause this reaction are not well known, and the reactions are often confused with true food allergies because they display similar symptoms. Anaphylactic shock is one of the most startling symptoms associated with food allergies, and such food intolerances, and may affect the gastrointestinal tract, skin, respiratory tract and the cardiovascular system. It can cause severe hypotension, and if not treated properly, it may lead to death within minutes after ingesting the offending food (Taylor 2000).

The rest of this chapter will focus on describing some of the properties of the nine most common food allergens and methods for detecting allergens.

MILK ALLERGENS

Milk is a nutritional biological fluid secreted from the mammary gland of female mammalians, and it is primarily intended to

provide nutritional requirements of neonates. Human milk and the milks of dairy animals, such as cows, goats, sheep and buffaloes, have been extensively studied. Humans are the only known mammals that consume the milk of other mammals, particularly from cows. In fact, cow's milk and cow's milk-associated food have been deeply rooted as an important part of the human diet, and the dairy industry plays a huge role in supporting nutrition of humans and continues to be a backbone of the agri-food sector in many countries.

In developed countries, bovine milk and milk-derived products contribute about 19% of total dietary protein intake and 73% of calcium intake (Tome et al. 2004). However, for some people, consumption of cow's milk and cow's milk-derived food has to be avoided due to milk allergy. Recent studies have indicated that prevalence and persistence of cow's milk allergy (CMA) in industrialised countries may be increasing. In North America, incidence of CMA is estimated at 2.5% in children and about 1% in the adult population with a 75% outgrowing rate at the age of 16 (Sicherer and Sampson 2010).

MILK PROTEIN

Milk protein is a very complex mixture of molecules. Thanks to advanced analytical techniques, over 200 types of proteins have been identified in bovine milk (Ng-Kwai-Hang 2002). These proteins can be arranged into five groups: caseins, whey proteins, milk fat globule proteins, enzymes and minor miscellaneous proteins. Caseins and whey proteins make up almost all of the total milk protein composition, whereas the other 3 groups are found in trace amounts (Table 42.1). Caseins can be separated from the other proteins by acid precipitation at pH 4.6 to form a coagulum. However, the ratio of casein and whey in the milk varies among different species. In human milk, the ratio is 40:60, in equine the ratio is 50:50 and in major dairy animals (cows, goats, sheep and buffaloes) the ratio is 80:20.

MAJOR MILK ALLERGENS

β-Lactoglobulin (BLG, not found in human milk) and caseins, α-s1-casein in particular, are regarded as the principal allergens in cow's milk (Kaminogawa and Totsuka 2003). A recent study of 115 CMA Japanese children identified casein as a major milk allergen with 107 (97.3%) children reacting positively to casein-specific IgE, whereas 51 patients (46.6%) were positive to BLG-specific IgE (Nakano et al. 2010). However, studies on large populations show that a high proportion of CMA patients are sensitised to multiple milk proteins, including proteins present in very low quantities, such as bovine serum albumin (BSA), immunoglobulins and lactoferrin, suggesting that all milk proteins could be potentially allergenic. Sensitisation to caseins, BLG, and α-lactalbumin (ALA) appear to be closely linked. However, sensitivity to BSA seems to be completely independent. Epitope mapping of major milk allergens has revealed multiple allergenic epitopic regions within each protein (Busse et al. 2002, Cocco et al. 2003).

Caseins

Casein (CN) forms the main fraction of milk proteins and is subdivided into a number of families, including α-S1-, α-S2-, β-, κ- and γ-caseins.

The α-S1-casein (α-S1-CN) is a single-chain phosphoprotein of 199 amino acid residues and represents about 40% of total casein. α-S1-CN is characterised by a high content of proline residues without disulfide bonds and the presence of a small amount of secondary structure, such as α-helix or β-sheets. Several epitope regions of α-S1-CN recognised by human IgE antibodies have been identified. These regions include amino acid (aa) 19–30, aa86–103 and aa141–150 (Spuergin et al. 1996), aa181–199 (Nakajima-Adachi et al. 1998) and nine regions from amino acid residues 17 through 194 (Chatchatee et al. 2001). Reasons for the differences in the dominant

Table 42.1. Characteristics of the Major Proteins in Human and Cow's Milk

Proteins	Human (mg/mL)	Cow (mg/mL)	Molecular Weight (kDa) of Cow's Milk Proteins	Number of Amino Acids in Cow's Milk
Whole caseins				
α-s1-Casein	0	11.6	23.6	199
α-s2-Casein	0	3	25.2	207
β-Casein	2.2	9.6	24	209
κ-Casein	0.4	3.6	19	169
γ-Casein	0	1.6	11.6–20.5	
Whey proteins				
β-Lactoglobulin	0	3	5.3	162
α-Lactalbumin	2.2	1.2	4.8	123
Immunoglobulins	0.8	0.6	<150	
Serum albumin	0.4	0.4	66.4	582
Lactoferrin	1.4	0.3	76.2	703
Other	1.3	0.6		

epitopic regions reported by different researchers may be due to racial (Kaminogawa and Totsuka 2003), dietary, breed and environmental differences.

The α-s2-casein is comprised of 207 amino acids and has one disulfide bond (Wal 1998). The α-S2-CN family accounts for 12.5% of the casein fraction and is the most hydrophilic among all caseins due to the presence of clusters of anionic groups. Ten IgE-binding regions have been identified between amino acid positions 31–200 of α-s2-casein (Busse et al. 2002).

β-Casein (β-CN) represents 35% of the total caseins and is quite complex because of the action of native milk protease plasmin. Plasmin cleaves β-CN and thereby generates γ1-, γ2-, and γ3-CN fragments. β-CN is the most hydrophobic component among casein fractions. Six major and three minor IgE-binding epitopes, as well as eight major and one minor IgG-binding regions, have been identified on β-CN (Chatchatee et al. 2001).

κ-CN accounts for 12.5% of the total casein fraction. Eight major IgE-binding epitopes, as well as two major and two minor IgG-binding epitopes, have been detected in κ-casein (Chatchatee et al. 2001).

β-Lactoglobulin

Bovine BLG is the most abundant whey protein and represent 50% of total whey proteins. It has no homologous counterpart in human milk. It possesses three disulfide bridges. BLG is relatively resistant to proteases and acid hydrolysis. BLG belongs to the lipocalin superfamily and is capable of binding a wide range of molecules, including retinol, β-carotene, saturated and unsaturated fatty acids and aliphatic hydrocarbons (Breiteneder and Mills 2005). BLG epitopes reported as markers for persistent CMA include aa1–16, aa31–48, aa47–60, aa67–78 and aa75–86 (Jarvinen et al. 2001, Inoue et al. 2001).

α-Lactalbumin

Bovine ALA is characterised by four disulfide bridges and possesses a high-affinity binding site for calcium, which stabilises its secondary structure.

Bovine ALA shows a 72% amino acid sequence homology to human ALA and is, thus, an ideal protein for the nutrition of human infants. Four different linear IgE-binding peptides, aa1–16, aa3–26, aa47–58 and aa93–102, have been identified by epitope mapping in children who outgrow CMA later in life (Jarvinen et al. 2001).

Bovine Serum Albumin

BSA accounts for about 5% of total whey proteins and is physically and immunologically very similar to human blood serum albumin. BSA has 17 disulfide bonds and most of the disulfide bonds are protected in the core of the protein and are therefore not easily accessible (Restani et al. 2004). This may be the reason for its relatively stable tertiary structure. IgE-binding epitopes identified for BSA have been inconsistent among studies (Karjalainen et al. 1992).

Lactoferrin

Lactoferrin (LF) is a milk-specific iron-binding protein. Although LF in cow's milk is homologous to human LF, the content is lower than that of human's milk. Its main function is to defend the host against infections and inflammations due to its ability to sequester iron from the environment, thereby removing this essential nutrient for bacterial growth (Ward et al. 2002). Despite its low concentration in bovine milk, LF-specific IgE have been detected in 45% of CMA patients (Wal 1998).

MILK ALLERGEN CROSS-REACTIVITIES

Different species of milk-producing ruminants have the same or closely related milk proteins with relatively similar ratios of casein and whey (Monaci et al. 2006). Furthermore, considerably high amino acid sequence homology (varying from 87–96%) exists among major milk proteins of cow, goat and ewe (Table 42.2). As a result, IgE cross-reactivity among the milk of goat, ewe and cow has been reported for most CMA patients. IgE sensitisation to sheep and goat casein has been found to be as high as 93–98% in children with IgE-mediated CMA (Besler et al. 2002a). In general, the milk of other ruminants is not a good alternative for CMA patients.

Cross-reactivity between cow's milk allergens and soya bean proteins has also been reported. Allergic reactions to soya bean was observed in about 17–47% of children with CMA (Hill et al. 1999). Cross-reactivity between soya bean and casein was confirmed by Rozenfeld et al. (2002), who showed that glycinin-like protein (two polypeptides, A5-B3) from soya bean were able to bind casein-specific monoclonal antibodies.

THRESHOLD DOSE

There is limited data on the threshold dose required to provoke a milk allergy reaction. Several research groups using double blind placebo controlled food challenges with milk protein have used doses varying from 0.6 to 180 mg to induce allergic reactions in CMA patients (Monaci et al. 2006). However, these studies were primarily intended for diagnostic purpose and not necessarily for determining the lowest provoking dose. Severe adverse reactions

Table 42.2. Comparisons of the Amino Acid Sequence Homology of the Major Proteins Found in Cow's Milk and That of Goat and Ewe

Milk Proteins	Sequence Homology (%)	
	Cow vs Goat	Cow vs Ewe
β-Lactoglobulin	96	96
α-Lactalbumin	95	94
α-s1-Casein	87	89
α-s2-Casein	88	89
β-Casein	90	90
κ-Casein	85	84

Source: Adapted from Wal 2004.

have been reported after eating food contaminated with trace amounts of milk protein, including breast milk from mothers who consume cow's milk (Gerrard and Shenassa 1983), meat treated with casein to enhance texture (Yman et al. 1994), frozen desserts that contain trace amounts of whey protein (Laoprasert et al. 1998) and lactose-containing medications that contained residual milk protein (Nowak-Wegrzyn et al. 2004).

Bindslev-Jensen et al. (2002) developed a statistical approach to estimate threshold levels of four major food allergens. They reported that the threshold dose required for a person to develop an adverse reaction using a million CMP susceptible population is 0.005 mg of cow's milk or 7×10^{-5} mg of milk protein (Bindslev-Jensen et al. 2002). Other workers have reported threshold levels ranging between 3 and 180 mg (Morisset et al. 2003a, Taylor et al. 2002).

EFFECT OF PROCESSING ON THE ALLERGENICITY OF COW'S MILK PROTEINS

Processing techniques are routinely applied to raw milk in order to reduce or eliminate microorganisms and enhance shelf life. Some of the techniques such as homogenisation, pasteurisation and sterilisation do not modify protein structure significantly, whereas others such as hydrolysis and irradiation do. In general, results from several studies have shown that cow's milk allergenicity could be decreased, increased or unchanged by processing treatments such as pasteurisation or sterilisation and homogenisation (Host and Samuelsson 1988).

Heat treatment

The effect of heating on milk protein allergenicity remains controversial. Pasteurised milk has been reported to have higher allergenicity than raw or homogenised milk (Host and Samuelsson 1988). Caseins are more thermostable, whereas BLG manifests a thermolabile behaviour (Wal 2004). However, BLG may be protected from denaturation when heated due to possible interactions with caseins. Currently, heat denaturation is not accepted as a satisfactory process to reduce the allergenicity of milk protein. On the contrary, application of heat treatment could lead to the formation of neo-allergens.

Hydrolysis

Hydrolysis of milk proteins reduces their allergenicity to varying degrees. Several cow's milk proteins, for example BLG, are relatively resistant to degradation by proteolytic enzymes, while others are considered very labile (e.g. caseins). Boza et al. (1994) obtained an extensively hydrolysed hypoallergenic infant formulae by using a combination of ultrafiltration process and hydrolysis with enzymes from bacterial/fungal origin with broad specificity. Extensively hydrolyzed formulas (eHF) successfully protect the development of allergy symptoms in the majority of CMA infants (Walker-Smith 2003). However, even eHFs (molecular weight (MW) less than 1.5 kDa) can still induce allergic response in infants with atopic family background (Nentwich et al. 2001) and CMA infants (De Boissieu et al.

1997). Moreover, eHF have also been criticised for their poor functionality (Crittenden and Bennett 2005).

Radiation

Lee et al. (2001) reported that the application of gamma irradiation to α-casein and BLG altered the epitope structure of both milk proteins, probably due to agglomeration of the milk proteins and consequent decrease in solubility. Further research is needed to clearly elucidate the effect of irradiated milk on allergenicity.

High-Pressure Treatment

High pressure may reveal potentially immunogenic hydrophobic regions to enzymes, resulting in better hydrolysis. Bonomi et al. (2003) reported that enzymatic hydrolysis under high pressure (600 MPa) produced non-immunogenic peptides. Other workers have, however, reported an increase in antigenicity of milk proteins on high-pressure treatment in the absence of hydrolysis (Kleber et al. 2004, 2007). Thus, as with irradiation, further research will be useful to ascertain the effect of high pressure on milk protein allergenicity.

EGG ALLERGENS

Egg protein is used as a protein nutritional standard because it is highly nutritional and has all the essential amino acids in the right amounts required by the human body. Moreover, with the exception of vitamin C, eggs serve as a good source of vitamins A, D, E, K, as well as the B vitamins. Whole egg and egg-derived ingredients also possess excellent functional properties (e.g. gelation, emulsification and foaming), which has resulted in their extensive use in the formulation of various food products.

Egg consists of the white and yolk, both of which contain allergenic proteins. Whole egg contains 12.8–13.4% protein, 10.5–11.8% fat, 0.3–1% carbohydrate and 0.8–1.0% ash on a wet basis (Breeding and Beyer 2000). Proteins found in egg white are ovalbumin, conalbumin, ovomucoid, lysozyme, ovomucin and other minor albumen proteins such as avidin, ovoglobulins, flavoprotein and ovoinhibitors. The egg yolk proteins are rich in lipoproteins and phosophoproteins and primarily comprise of lipovitellin, lipovitellenin, vitellin, vitellenin, phosvitin, transferrin, γ-globulin, serum albumin and α_2-glycoprotein.

PREVALENCE, SYMPTOMS AND THRESHOLDS

Although the majority of people can tolerate eggs in their diet, a small percentage of the population, mostly children, suffer severe allergic reactions after consuming egg. Symptoms of egg allergic reactions include vomiting, diarrhoea, gastrointestinal pain, urticaria, angiodema, atopic dermatitis, asthma and rhicoconjunctivitis (Martorell Aragonés et al. 2001).

Egg allergy prevalence in the general population is estimated between 1.6 and 3.2%, making egg the second most important cause of food allergic reactions next to peanut (Arede et al. 2000, Mine and Yang 2008 and references within). In children, egg

allergy is the most commonly occurring food hypersensitivity with symptoms usually becoming evident in the child's first year.

Major Egg Allergens

Egg white is more allergenic than the egg yolk. Ovalbumin and ovocumoid, the two most potent egg allergens together make up about 65% of the composition of egg white proteins. Ovalbumin has a MW of 44.5 kDa and contains 385 amino acids. Using pooled sera from 18 egg-allergic patients, Mine and Rupa (2003) identified five IgE binding linear epitopes in the primary structure of the protein. Four of the five epitopes were exposed at the surface of the protein.

Ovomucoid, the other major allergen, is a 28 kDa MW protein comprising 186 amino acids. The protein has three structurally distinct domains (Domain I, II and III), which are cross-linked by disulfide bonds. Several linear sequences representing allergenic epitopes recognised by both IgE and IgG antibodies have been identified (Zhang and Mine 1998, Mine and Zhang 2002). Ovomucoid also contains 20–25% carbohydrate moieties. Most reports indicate that the carbohydrate moieties are not immunogenic; however, some studies suggest that the carbohydrate region in the third domain is immunologically active (Mine and Rupa 2004). Ovomucoid is relatively stable to digestion, and heat and allergenic fragments have been detected even after digestion by pepsin.

Other reported egg allergens are ovotransferrin (MW 76 kDa) and lysozyme (MW 14.3 kDa). Aabin et al. (1996) reported a higher frequency of reactivity for ovotransferrin (53%) than for ovomucoid (38%) and ovalbumin (32%), suggesting that it may be a more important allergen than the latter two. The same authors reported frequency of reactivity of 15% for lysozyme. Very few studies have reported on the allergenicity of egg yolk proteins; however, some of the allergenic proteins identified in egg yolk include apovitellenin I, apovitellenin VI and phosvitin (Walsh et al. 1988, 2005).

Thresholds of Clinical Reactivity to Eggs

Reported thresholds of clinical reactivity to eggs range between 0.13 and 6.5 mg of hen's egg protein (Morisset et al. 2003a, Taylor et al. 2004). As with other allergens, there are currently no cures for egg allergy, and the best management tool is the reading of food labels and avoidance of foods containing egg or egg-derived ingredients. The use of multiple definitions for eggs and egg ingredients (e.g. albumin, albumen, conalbumin, egg nog, egg yolk, egg white, lecithin, livetin, lysozyme, ovalbumin, ovoglobulin, ovomacroglobulin, ovomucin, ovomucoid, ovomucin, ovovitellin, ovotransferrin and vitellin) in the past made egg avoidance challenging. Today, most countries in North America as well as in Europe require the use of the common names of priority allergens when they are used as ingredients in foods or are likely to be present in foods in spite of best efforts to control their presence. Fortunately, most children outgrow their egg allergy by school age (Heine et al. 2006). Egg allergy, however, tends to persist in children with positive skin tests, multiple allergies and/or who have more severe reactions (e.g.

respiratory symptoms, angiodema and multisystemic reactions) or other atopic diseases such as asthma (Ford and Taylor 1982, Mine and Yang 2008).

SOYA BEAN ALLERGENS

Soya bean (*Glycine max*) is a legume belonging to the *fabaceae* family and the *glycine* genus. On a dry basis, soya beans contain 35–40% protein, 17–23% lipid, 31% carbohydrate and 4–5% minerals. Soya bean is considered as one of the most nutritional plant sources of food providing a well-balanced amino acid profile and good supplies of omega 3 and omega 6 fatty acids. The history of the seed dates as far back as 3000–5000 years, with its origins somewhere in Asia.

Consumption of soya bean and soya bean foods has been linked to many health benefits. Various studies have reported associations between soya bean consumption and reduced risk of cardiovascular disease, cancer, diabetes, bone loss and menopausal symptoms amongst others (Friedman and Brandon 2001, Hori et al. 2001, Chen et al. 2003, Zhang et al. 2003, Stephenson et al. 2005, Anderson 2008). These reports have fuelled the growth of soya foods in Western countries. In October 1999, the Food and Drug Administration of the United States approved a health claim linking the consumption of 25 grams of soya protein a day (as part of a diet low in saturated fatty acids) to reduced cardiovascular disease risk (FDA 1999). For manufacturers to make this claim, products must provide at least 6.25 grams of soya protein per serving. Soya flour and soya protein ingredients are therefore increasingly being used in many food products.

Unfortunately, soya bean is listed in Canada, the United States, Australia and the European Union as a priority allergen, requiring labelling when it is used as an ingredient in foods. Symptoms of soya bean allergy are similar to the other major allergens and include cutaneous, respiratory as well as gastrointestinal responses. Although the majority of allergic responses occur on ingestion, allergic reactions on inhalation of soya bean and soya bean byproducts has also been reported (Gonzalez et al. 1992, 1995, Codina et al. 1997).

Major Soya Allergens

Over 17 different allergens have been identified in soya bean. These include soya bean glycinin (11S), β-conglycinin (7S), soya bean vacuolar protein (Gly m Bd 30K or P34), the Kunitz trypsin inhibitor (KTI), Gly m Bd 28K, soya bean profilin (Gly m 3), soya bean hull proteins (Gly m 1.0101, Gly m 1.0102, Gly m 2) and the pathogensis-related (PR) soya bean protein SAM22 (Gly m 4) (Wilson et al. 2005, L'Hocine and Boye 2007, Boye et al. 2010).

Glycinin and β-conglycinin have been studied extensively as they are the major soya bean storage proteins and represent over 70% of the proteins found in soya (Liu 1997). They are both globulins belonging to the cupin superfamily (Breiteneder and Radauer 2004) and have complex quaternary structures with conserved amino acid sequence homology. Glycinin

(MW $\sim$ 300 kDa) has a hexameric structure with each monomer comprising an acidic and basic subunit linked by disulfide bonds. β-conglycinin (MW $\sim$ 150 kDa) has a trimeric structure with the three major subunits α, α' and β having MWs of 76, 72 and 53 kDa, respectively (Liu 1997, Krishnan 2000). Various studies have shown that all glycinin and β-conglycinin subunits bind IgE from soya bean-allergic patients although a few studies have found an absence of binding to some subunits (Pedersen and Djurtoft 1989, Krishnan et al. 2009, Boye et al. 2010).

The soya bean vacuolar protein (P34; MW of 34 kDa), which is an oil body-associated protein, is also a major soya allergen. Over 65% of soya bean-allergic patients reportedly react to it (Ogawa et al. 1991, 1993). The KTI, which is a 21 kDa belonging to the plant defence system, is another important allergen. KTI exerts its effect by inhibiting the activity of proteases such as trypsin. Although the major allergenic epitopes have not been identified, reports suggest that it may be a culprit in soya bean-induced occupational respiratory disorders (Baur et al. 1996) along with the soya bean hydrophobic lipid transfer proteins identified in soya bean hulls (Gonzalez et al. 1992, 1995).

PREVALENCE, SYMPTOMS AND THRESHOLD

Prevalence rates of soya allergy range between 0.3% and 0.4% (Becker et al. 2004, Sicherer and Sampson 2006). The exact amount of soya proteins required to induce an allergic response is, however, not known. Reported threshold levels vary significantly and range between 0.0013 and 500 mg of soya protein (Bindslev-Jensen et al. 2002, Ballmer-Weber et al. 2007).

EFFECT OF PROCESSING ON SOYA ALLERGENS

In general, processing treatments such as thermal treatment, microwaving, irradiation, hydrolysis and fermentation have not been shown to remove soya bean allergenicity. Some treatments may cause modifications in proteins structure and hide allergenic epitopes reducing but not eliminating their immunogenicity, whereas other treatments cause unfolding of the proteins, allowing greater exposure of hidden allergenic epitopes and increasing the immunogenic properties of the proteins (Davis and Williams 1998, Soler-Rivas and Wichers 2001).

Soya bean is processed into products such as soya beverages, tofu, edamame, miso, natto and tempeh. The beans can also be processed to obtain soya oil, soya flour, soya lecithin, soya fibre, soya protein concentrate (>65% protein on dry basis), soya protein isolate (>90% protein on dry basis), textured soya products and soya hydrolysates or hydrolysed vegetable protein, which are used in a wide variety of products. Other novel applications include soya ice cream and soya yogurt. Allergenicity of soya foods is linked to the presence of residual soya proteins in these foods, so unless the soya ingredient used is highly refined (e.g. refined soya bean oil), it is likely to contain allergenic protein and must be labelled when used in foods. Studies conducted on soya lecithin have generally reported little or no allergy risk to sensitised individuals (Awazuhara et al. 1998); however, hydrolysed and fermented soya products tend to retain some of their allergenic properties (Hefle et al. 2005, L'Hocine and Boye

2007). Appropriate caution therefore needs to be exercised in the consumption of processed soya foods.

SOYA ALLERGEN CROSS-REACTIVITIES

Although not confirmed clinically, a high cross-reactivity has been reported for different legumes (soya bean, peanut, lentils and beans; Yunginger 1990, Eigenmann et al. 1996, Kalogeromitros et al. 1996). This may be explained by the high amino acid sequence homology, which frequently occurs in plant proteins belonging to the same family. Clinical co-reactivity rates in peanut-allergic patients for soya using placebo-controlled challenges range between 1% and 6.5% (Burks et al. 1988). Additionally, coexisting clinical reactivity has been reported between soya bean and cow's milk for some allergic patients ranging between 5% and 50% depending on the specific group of patients studied (Host and Halken 1990, Burks et al. 1994).

PEANUT AND TREE NUT ALLERGENS

Peanuts and tree nuts contain some of the most potent food allergens. Prevalence rates of 0.8–1.5% for peanut allergy in the UK and US population and about 0.6% for tree-nut allergy in the US population have been reported (Grundy et al. 2002, Sicherer et al. 2003). Nuts and tree nuts belong to different plant species; however, they are frequently discussed together as their presence, handling and use in the food chain as well as the allergic responses they induce are often similar.

Peanut (*Arachis hypogea*) is a legume belonging to the family *Leguminosae*. It grows under the ground in peanut pods containing the peanut seed. Tree nuts, on the other hand, are edible seeds that grow on trees. Examples of tree nuts that are of most concern as allergens are hazelnut (*Corylus avellana*), almond (*Prunus dulcis*), pistachio (*Pistachia vera*), macadamia nuts (*Macadamia integrifolia*), cashew (*Anacardium occidentale*), walnut (*Juglans regia*), pine nut (*Pinus pinea*), pecans (*Carya illinoinensis*) and Brazil nut (*Bertholetia excelssa*).

PREVALENCE AND THRESHOLD

Prevalence rates of peanut and tree nut allergies vary for different populations but appear to be higher in Western societies such as in Europe and North America. Reported rates vary from 0.2 to 1.7 for peanut and 0.1 to 1.4 for tree nuts (Sicherer et al. 2003). Allergic responses following ingestion of peanut and tree nuts by allergic patients range from oral pruritus, nausea, vomiting, urticaria, angiodema, bronchospasm, bronchitis, hypotension, anaphylaxis and death in some instances. The reaction often occurs within minutes to a few hours after food consumption, and the severity of the response may be exacerbated by preexisting asthma (Sampson 2002, Sicherer et al. 2003).

Threshold doses for clinical reactivity reported in the literature range from 100 μg to 10 mg for peanut and 20 μg to 7.5 mg for tree nuts (Hourihane et al. 1997, FDA 2006). Cross-reactivities between peanut, soya bean as well as other tree nuts have been reported (de Leon et al. 2003).

MAJOR PEANUT AND TREE NUT ALLERGENS

The major allergens identified in peanut are Ara h 1 (glycoprotein, vicilin, MW 63.5 kDa), Ara h 2 (glycoprotein, conglutin, MW 17.5 kDa), Ara h 3 (legumin, MW ~ 60 kDa), Ara h 4 (legumin, MW 37 kDa), Ara h 5 (profilin, MW 14–15 kDa), Ara h 6 (conglutin, MW 14.5 kDa), Ara h 7 (conglutin, MW 15.8 kDa) and Ara h 8 (pathogenesis-related protein, MW 16.9 kDa; Wen et al. 2007, Rajamohamed and Boye 2010). Ara h 1 and Ara h 2 are classified as major allergens and are recognised by the sera of >90% of peanut-allergic patients. Ara h 3, Ara h 4, Ara h 5, Ara h 6, Ara h 7 and Ara h 8 are less frequently recognised by the sera of peanut allergic individuals and are classified as minor allergens (Wen et al. 2007, Rajamohamed and Boye 2010).

Allergenic proteins in tree nuts vary depending on the type of nuts. In a voluntary survey report on tree nut allergy conducted by Sicherer et al. (2001), 46% of tree-nut-allergic individuals reacted to multiple tree nuts, and 54% reacted to single tree nuts with the highest reactions being reported toward walnut (34%), cashew (20%) and almond (15%) and lower allergic responses to pecan (9%), pistachio (7%), hazelnut, Brazil nut, macadamia nut, pine nut and hickory (less than 5% each). Table 42.3 provides a list of some of the major proteins identified in tree nuts and their properties (Rajamohamed and Boye 2010).

PROCESSING-INDUCED CHANGES IN PEANUT AND TREE NUT ALLERGENIC PROTEINS

Processing induces changes in peanut and tree nut proteins, which can modify their allergenic properties. Many research studies have found, for example, that roasting increases the immunogenic properties of peanut compared to frying and boiling. Using sera of peanut-allergic patients, Beyer et al. (2001) found lower IgE-binding intensities of Ara h 1, Ara h 2 and Ara h 3 in fried and boiled peanuts compared to roasted peanuts. Similarly, Maleki et al. (2000) found significant increases in the allergenic properties of roasted peanut compared to raw peanut. On the contrary, Koppelman et al. (1999) reported no change in the allergenicity of Ara h 1 on heat treatment. Hansen et al. (2003) also reported that dry roasting of hazelnut reduced its allergenicity compared to raw hazel nut. Differences in the effect of the thermal treatment on the molecular structure of the proteins and their solubility may explain the variations in the responses reported.

FISH AND SHELLFISH ALLERGENS

Fish and shellfish represent one of the most common sources of food allergens in the adult population. Fish and shellfish species known to cause allergic reactions include but are not limited to cod, flounder, grouper, haddock, halibut, hake, herring, mackerel, pike, sole, snapper, trout, crabs, lobsters, prawns, shrimps, crayfish, octopus, squid, clams, mussels, oysters, scallops and snails.

The major allergen in fish is parvalbumin (Gad c 1), a 12 kDa protein (O'Neil et al. 1993). Tropomyosin, with a MW of ~36 kDa, is the major allergen found in shrimp, lobster, crab and molluscs such as squid, oyster, snail, mussels, clam and scallops (Daul et al. 1993a, 1993b). Both parvalbumin

Table 42.3. Major Tree-Nut Allergens and Their Characteristics

Tree Nuts	Allergen	Molecular Weight (kDa)	Protein Family	Allergen Type	Identified Epitopes	Allergen Stability	References
Cashew	Ana o 1	50	Vicilin (7S)	Major	11	Thermostable	51, 54

MW, molecular weight; NR, - not reported; PR, pathogenesis-related protein family; LTP, lipid transfer protein.

and tropomyosin are muscle cell proteins. To date, eight major IgE-binding epiopes have been identified in shrimp tropomyosin (Lehrer et al. 2003).

Exposure, including handling, consumption and inhalation of air-borne particles from fish and fish ingredients, can induce allergic reaction in sensitised individuals. Seafood-induced allergic reactions are generally similar to responses induced by many of the other allergenic foods. A study conducted using 30 shrimp-sensitive and 37 fish-allergic individuals reported allergic symptoms ranging from generalised itching, urticaria to swelling of the lips and tongue (Lehrer et al. 2003). Other reported symptoms include difficulty breathing, gastrointestinal distress and anaphylactic shock (O'Neil et al. 1993, Daul et al. 1993a, 1993b).

Additionally, occupational reactions among a variety of seafood workers (e.g. fish and prawn workers, seafood processing workers, fishermen, canners, restaurant cooks and other workers in the seafood industry) have been reported. Cartier et al. (1984) showed that workers in the seafood industry were exposed to occupational allergens through direct contact with seafood products as well as inhalation of bits of seafood or water droplets generated during processing. Out of the 303 crab workers investigated, 18% reported rhinitis or conjunctivitis, about 24% some sort of skin rash and over a third reported of asthma.

Very little work has been done on the effect of processing on the allergenicity of seafood. As with other allergens, highly refined products from seafoods that do not contain residual proteins (e.g. refined fish oils, gelatine and isinglass) do not pose a risk to allergic consumers. However, processing techniques that leave seafood protein fragments in the finished product may pose serious allergenic risk to sensitised individuals. As consumers and the food industry become increasingly aware of the health benefits of fish, consumption and utilisation of fish and fish products is likely to increase, which could increase the allergen risk for fish- and shellfish-sensitised individuals.

ALLERGENS IN CEREALS

Certain cereal grains contain proteins that induce immune-mediated responses in individuals who are predisposed to CD or who have specific cereal allergy. As the mechanisms involved in celiac disease are distinctly different from those involved in IgE-mediated cereal allergy, they will be discussed separately.

CELIAC DISEASE

CD also sometimes known as gluten-sensitive enteropathy or gluten intolerance is an abnormal immunological response to gluten/gliadin, which frequently results in a diseased state characterised by damage of the lining of the gut (villous atrophy). In these individuals, the T lymphocytes in the small intestines respond abnormally to gluten, causing inflammation and damage to the absorptive epithelium of the small intestine, resulting in malabsorption and disorders such as diarrhoea, bloating, weight loss, anaemia, weakness and muscle cramps. In children, CD leads to growth retardation and underweight. Symptoms linger for some days even after the offending food is avoided due to the fact that the damaged intestine requires time to heal. Mortality rate has not been reported but patients are likely to develop malignant lymphomas (Ferguson 1997).

CD occurs more commonly in Caucasians than in Blacks, Asians and Hispanics according to present knowledge. Whether this is due to under-diagnosis or true biosocial/genetic difference is not clear. Reported prevalence rates are 1:200–400 in Europe, 1:133 in America, 1:100–300 in a UK study and 1:120 in a Belfast study (Rostami et al. 1999, Gomez et al. 2001, Fasano and Catassi 2001, Fasano et al. 2003, García Novo et al. 2007). CD appears to be genetic with 10% prevalence rates reported among first-degree relatives of CD patients and 70–100% concordance rates amongst twins. Higher prevalence rates are reported in women likely due to higher rates of diagnoses.

The primary offending foods for celiacs are wheat, barley and rye. The major proteins present in these cereals are albumins, globulins, gliadin (prolamin) and glutenin (glutelin) and the offending protein for celiacs is the gluten fraction in these cereals, which are the prolamins and glutelins, particularly the prolamins (i.e. hordein (barley), secalin (rye) and gliadin (wheat)). Several repeating peptide sequences (e.g. QQPFP, QQQP, QQPY, QPYP, PSQQ) in the primary structure of these proteins have been blamed (Osman et al. 2001, Kahlenberg et al. 2006, Darewicz et al. 2008). Although the mechanism involved in the pathogenesis of the disease is unclear, tissue transglutaminase is believed to play a key role in the deamidation of glutamine converting it to glutamic acid, which allows the immune cells to bind, provoking continued immune response (Anderson et al. 2000, Mazzeo et al. 2003). The principal organ targeted is the gut (i.e. small intestine); however, damage to other parts of the body such as the skin (dermatitis herpetiformis), the teeth and the liver has been reported (Lohi 2010). Severity of the disease increases significantly with delays in diagnosis (i.e. age of diagnosis) and the degree of susceptibility increase with the rate of gluten consumption (quantity). Tolerance thresholds for the general population of CD patients are not known but some workers have reported values ranging between 10 and 100 mg gluten (Collin et al. 2004, Hischenhuber et al. 2006, Catassi et al. 2007).

IgE-MEDIATED CEREAL ALLERGY

IgE-mediated cereal allergy is distinctly different from CD. This type of allergy is an immediate-type hypersensitivity occurring minutes to hours after consumption of the offending food. Symptoms are similar to those described for the other allergens and include oral allergy syndrome (e.g. swelling of lips), respiratory difficulties (e.g. asthma), skin reaction (e.g. eczema, atopic dermatitis) and gastrointestinal distress (e.g. nausea, diarrhoea, vomiting and cramps). There is no accurate data available on the prevalence, but as is the case for the other allergens, genetic susceptibility has been suggested (Becker et al. 2004). Severity of IgE-mediated cereal allergy depends on the immune state of the patient (degree of sensitisation/tolerance) and the concentration

of antigen in the food consumed. The proteins responsible for this type of allergy can be the albumins, globulin, gliadins or glutenins and will vary depending on the individual and the specific allergenic food. Offending foods include buckwheat, rice, corn, millet, wheat, oats, rye and barley (Cantani 2008). Buckwheat and rice allergies are more frequently observed in Asia than in Europe or North America (Taylor and Hefle 2001, Kumar et al. 2007). The pathway for sensitisation and cereal allergy elicitation is by ingestion (mouth) and/or inhalation (nose) (e.g. baker's asthma). Wheat allergy is responsible for up to 30% of occupational asthma in the bakery industry.

Another type of cereal allergy is exercise-induced cereal allergy. Symptoms in this case appear only after food allergen consumption is followed by exercise. Wheat, as well as shellfish and nuts, is mostly associated with this type of allergy (Romano et al. 2001, Beaudouin et al. 2006, Porcel et al. 2006).

Foods to Avoid for Gluten-Sensitive Enteropathy Patients and IgE-Mediated Cereal-Allergic Patients

As with the other allergens, there are presently no cures for CD. Major foods to avoid include barley, wheat, durum, farina, kamut, rye, semolina, spelt and triticale. Oats was previously included in the list of gluten-containing foods; however, several recent studies suggest that quantities of oats of up to 50 g/day are harmless to the majority of gluten-sensitive individuals (Janatuinen et al. 1995, 2000, 2002, Lundin et al. 2003). A major challenge for the industry is that commercial oats is very frequently contaminated with high amounts of wheat, barley or rye (Thompson 2004, 2005) as these crops are often grown in the same regions and in close proximity. Furthermore, a small percentage of CD patients may react to oat proteins. The mechanisms at play in this instance and the specific proteins in oats to which these patients react still remain to be clarified. As gluten-containing cereals are often used as ingredients in food formulation, other foods to avoid include hydrolyzed vegetable protein, flavouring, malt, maltodextrin, malted barley, malt vinegar and starch from gluten sources, especially if these contain residual amounts of gluten proteins.

Many countries have adopted the gluten-free Codex Alimentarius Standards (Joint FAO/WHO Food Standards Programme and Codex Alimentarius Commission 2008), which sets a maximum limit of 20 ppm for gluten-free foods that are naturally free from gluten and 100 ppm for gluten-free foods that have been rendered gluten-free through processing.

For IgE-mediated cereal allergy, foods to avoid will depend on the particular allergy. Major challenges for cereal-allergic individuals are cross-reactivity and cross-contamination of foods. Food ingredients that are particularly problematic if not properly labelled are starches, spices, seasonings, sauces, flavourings, colourings, some vinegars, hydrolysed plant protein, syrups (e.g. brown rice syrup), beverages (e.g. beer, ale, etc.). Other potential hidden sources of cereals or cereal ingredients are cosmetics, pillows, toy stuffings and certain medications when products derived from these are used as ingredients.

SESAME AND MUSTARD ALLERGENS

Sesame Allergy

Sesame (*Sesamum indicum*) is a herbaceous plant of the *Pedaliaceae* family originating from India, which is now grown in many countries. It is also known as Benne, Gingelly, Til or Teel, Simsim and Ajonjoli and is now a common ingredient used extensively in everyday foods because of its high nutritional value (Perkins 2000). Sesame proteins are rich in methionine (Dalal et al. 2002, Wolff et al. 2003). Common sesame products include biscuits, crackers, breadsticks, rice cakes, etc., as well as prepacked delicatessen and processed foods such as noodles, dips, soups, sausages, samosas, processed meats, vegeburgers, chutneys, etc., (Perkins 2000, Allergyexpert 2010).

Sesame seeds, which may be used whole or crushed, are extremely potent allergens, causing severe allergic reactions in susceptible individuals. The first case of sesame allergy was reported in 1950 (Gangur et al. 2005). More recently, a study of Australian children showed that allergic reactions to sesame ranked fourth behind reactions to egg, milk, and peanuts, and sesame was also found to be the third most common allergy-inducing food in Israeli children (Gangur et al. 2005). Another recent study showed that sesame allergy in Israeli children was more common than peanut allergy (More 2009). Sesame allergy seems to affect people of all ages, which imply that this food allergy is not commonly outgrown. The symptoms of sesame allergy can include urticaria, angioedema, asthma, atopic dermatitis, oral allergy syndrome, allergic rhinitis and anaphylaxis.

One of the major sesame seed allergens is the 9 kDa, 2S albumin (Pastorello et al. 2001). Beyer et al. (2002) also identified 10 IgE-binding proteins in sesame, four of which had MWs of 7, 34, 45 and 78 kDa. Wolff et al. (2003) have also reported a 14 kDa sesame allergenic protein belonging to the 2S albumin family.

Sesame products are used in a wide variety of food products and may represent hidden allergens in foods. Fatal anaphylactic reactions have occurred as a result of consuming sesame (Gangur et al. 2005). Unrefined sesame oil may be used in food products, which may trigger allergic reactions in susceptible individuals. The oil resists rancidity and is popular with Oriental chefs. In the bakery industry, workers have reported allergic reactions, which include asthma, to sesame products. In addition to its use in the food industry, sesame and sesame products are used in the pharmaceutical and cosmetic industries. Sesame products used in cosmetics and ointments may cause allergic dermatitis, an inflammatory condition of the skin, in sensitised individuals. Contact dermatitis as a result of direct exposure to cosmetics or pharmaceutical products containing sesame allergens has been reported. Specific instances of sesame allergy resulting in skin rashes and inflammation after baking with sesame seeds and skin rashes from cosmetics that contain sesame oil have also been reported (Stoppler and Marks 2005).

As sesame allergens are similar in biochemical structure to peanut allergens, people with sesame allergy may be at risk of having allergic reactions as a result of eating peanuts and vice-versa (Gangur et al. 2005). Cross-reactivity may also exist with rye, kiwi, poppy seed and various tree nuts (such as hazelnut,

black walnut, cashew, macadamia and pistachio), but clinical studies are lacking.

While the number of reports of sesame allergy has steadily increased, it is still not clear whether this increase is in the number of reactions or an increased rate of detection and reporting of these allergic reactions (Stoppler and Marks 2005).

Mustard Seed Allergy

The mustard plant belongs to the family *Brassicaceae* with cabbage, cauliflower, broccoli, Brussel sprout, turnip and radish (Monreal et al. 1992). Mustard is often consumed as a condiment prepared from the mustard seed. The powder is made from a mixture of two species, *Sinapis alba* L. (yellow mustard) and *Brassica juncea* L. (oriental mustard). The varieties *Brassica nigra* and *Brassica juncea* are used for food products. In addition to mustard powder, mustard is also usually found in salad dressing, mayonnaise, soups and sauces (Ensminger et al. 1983).

Mustard allergy is now considered to be a very common food allergy, accounting for about 1.1% of food allergies in children (Morisset et al. 2003b) and ranks fourth in children's food allergies after eggs, peanuts and cow's milk (Rance et al. 2000). The major allergen of yellow mustard is Sin a 1, which has been found to be resistant to heating and proteolysis (Dominguez et al. 1990, Gonzalez de la Pena et al. 1996, Rance et al. 2000). Bra j 1 is the major allergen in oriental mustard with a structure similar to that of Sin a 1 (Gonzalez de la Pena et al. 1991, Caballero et al. 1994).

Mustard allergy can cause a wide array of symptoms. Rance et al. (2000) reported that allergic reactions to mustard start early in life and are probably linked to early consumption of baby foods. Mustard-allergic patients will react to any food that comes from the mustard plant, including jars of mustard, mustard powder, mustard leaves, seeds and flowers, sprouted mustard seeds, mustard oil and foods that contain these (Bock 2008).

Common symptoms of mustard allergy include difficulty in breathing, shortness of breath and other breathing complications, a rash or hives, itchy skin or general skin irritation. In some severe cases, it can lead to anaphylaxis, and if left untreated, anaphylaxis can lead to anaphylactic shock and even death. Some of the common symptoms of anaphylaxis include constriction of airways in the throat and lungs, anaphylactic shock, severe drop in blood pressure, heightened pulse and heavy heartbeat, dizziness, nausea and abdominal pain, confusion and disorientation, and loss of consciousness. Panconesi et al. (1980) reported the first case of mustard-induced anaphylaxis after the subject had consumed pizza.

Incidents of cross-reactions have been rarely reported. However, single cases have been described of cross-allergy to cauliflower, broccoli, cabbage and Brazil nuts, which may be linked to sequence homology of some proteins (Moneret-Vautrin 2006). One of the major challenges of mustard allergy is that many foods contain mustard even when it would seem unlikely (e.g. lunchmeat and hot dogs). Thus, careful reading of labels on processed foods is important for mustard-allergic patients.

MINOR FOOD ALLERGENS

As previously indicated, over 170 foods are known to provoke allergic reactions in humans (Taylor 2000). In addition to the nine major priority allergens, other minor food allergens and/or emerging allergens include lupin, pea, chickpea, lentil, fruits (e.g. apple, apricot, avocado, banana, cherry, grape, kiwi, mango, melon, peach, pear, pineapple and strawberry) and vegetables (celery, carrot, eggplant, lettuce, potato, pumpkin and tomato). The reader is referred to the following references for further reading (Pereira et al. 2002, Fernández-Rivas 2003, Fernández-Rivas et al. 2008, Harish Babu et al. 2008, Towell 2009, Skypala 2009, Jappe and Vieths 2010).

MANAGEMENT OF FOOD ALLERGY

Many of the priority food allergens such as milk, eggs, nuts and soya bean are commonly used in food processing (e.g. processed beef, sausages, salad dressings, breads, cakes, soups and sauces) and pharmaceutical products (e.g. casein hydrolysates as "drug" carriers) due to their desirable properties (Monaci et al. 2006). Extensive use of these foods as ingredients in various products increases the chances of their presence as hidden allergens, particularly when they are undeclared or present as a result of cross-contact.

As there are currently no cures for food allergy, the best management tool is the reading of food labels and avoidance of foods containing allergens or allergen-derived ingredients. As a result, many countries presently require the use of the common names of priority allergens when they are used as ingredients in foods.

A major development in the last decade has been the use of precautionary allergen labelling to warn allergic consumers of the likely presence of allergens. Unfortunately, consumers with food allergy have become less avoidant to products with advisory labels, such as "may contain" or "shared equipment" due to their misuse (Hefle et al. 2007). Pieretti et al. (2009) studied the use of advisory labels in the United States and found that 17% of 20,241 manufactured foods contained advisory labels. Thus, the unregulated use of advisory labels has become a source of confusion and frustration, which could eventually pose challenges for allergic consumers (Pieretti et al. 2009).

Recent emergence of the hygiene hypothesis (Yazdanbakhsh et al. 2002) brings a new approach for the management of allergic diseases. Several epidemiological studies have suggested that allergic diseases are more common in industrialised nations and urban areas compared to developing countries and rural areas. Less frequent microbial exposures in the developed world has been regarded as an important predisposing factor for having higher allergic population in these regions. To compensate the inadequate exposure of microbial load, probiotics (live bacteria, usually *Lactobacillus* and *Bifidobacterium)* are now being added in some infant formula along with oligosaccharides (prebiotics; Matricardi et al. 2003). The goal is to achieve the development of regulatory T cell or balanced Th1/Th2 activity, which could eventually prevent allergy development (Cross et al. 2001, Prioult et al. 2004). Further research will be required to confirm the purported effects.

Another area of interest is specific oral tolerance induction (SOTI). Taking milk as an example, about 15% of children with milk allergy maintain the susceptibility permanently in their life. Strict avoidance of cow's milk and cow's milk derivatives remains the gold standard for allergen management for such CMA patients. For these patients, however, the likelihood of exposing the offending allergen unintentionally always remains and thus total avoidance cannot be guaranteed. Similar concerns exist for patients with persistent peanut and tree nut allergies. SOTI is a promising approach particularly for patients with persistent food allergy. Staden et al. (2007) reported that SOTI treatment (using a daily dose of CMP, starting from 0.002 mg CMP) remarkably increased the threshold dose for allergic reaction in CMA patients. As a result, the patient could be protected against potentially fatal allergic reactions when small amounts of the hidden allergen are accidentally ingested. Since this approach uses the specific offending allergen to induce tolerance, development of mild to moderate side effects (such as itching in the mouth, nausea and wheals, etc.) is very common. Close supervision by an experienced professional is, therefore, necessary for SOTI treatment. Similar promising studies have been reported for peanut (Blumchen et al. 2008, Clark et al. 2009, Jones et al. 2009).

For the food industry, food allergen testing has become an increasingly important tool for the management and control of allergens during food production and processing. The rest of the chapter provides a brief summary of some of the methods currently available for allergen detection.

METHODS FOR DETECTING ALLERGENS

Table 42.4 provides examples of some of the commonly used methods for food allergen detection. Food allergens may be detected either by the presence of the target allergen itself or by using a marker in the target food. The method of choice will depend on factors such as food matrix interference, nature and quantity of the target allergen, the desired level of detection, specificity and time and resources required for running the assay. The threshold dose for sensitised individuals to manifest allergic reactions is quite low and variable among individuals (Bindslev-Jensen et al. 2002). However, it is commonly agreed that food allergen detection methods should be sensitive enough to detect 1–100 mg of analyte (allergen) per kg of processed food (Poms et al. 2004). Increasing numbers of rapid and user-friendly test kits to detect different food allergens are now commercially available with sensitivities ranging from 0.05 to 10 mg/kg (Table 42.5).

Protein-based food allergen detection methods include immunoblotting, rocket immunoelectrophoresis, enzyme allergosorbent test, enzyme-linked immunosorbent assay (ELISA), protein microarray and biosensors. More recently developed DNA-based methods are available as supplementary and complementary methods to protein-based methods and are particularly useful in species differentiation and detection of genetically modified food (Mustorp et al. 2008). This chapter will focus on ELISA-based detection, lateral-flow assays (LFA) and dipstick test, proteomic approaches and DNA-based allergen detection methods.

ELISA-BASED DETECTION METHODS

Among the growing number of food allergen detection techniques, ELISA has gained prominence and has become an extensively used technique due to its high sensitivity and specificity, availability of automation and user friendliness. Some ELISAs are designed to detect specific allergens (e.g. BLG, Ara h1 (a major peanut allergen) and shrimp tropomyosin), whereas other ELISAs detect mixtures of proteins from the allergenic source (e.g. total milk, egg, peanut and almond-soluble proteins; Taylor et al. 2009). Detection is based on binding of an allergen or a specific marker protein with an antibody specifically generated to recognise and bind to these proteins. This binding complex is visualised by a colourimetric assay when the enzymes, which are labelled to the allergen specific antibody, interact with the substrate solution. The concentration of the allergen can be quantified by obtaining optical density (OD) values with a microplate reader and plotting these values using a standard curve.

There are certain limitations of ELISA-based detection methods, however (Yeung 2006). ELISAs are based on aqueous systems and they do not work well in detecting insoluble proteins or allergens derived from edible oil-producing foods. In addition, ELISA may not detect oleosins, a family of protein involved in the formation of oil bodies in peanut and sesame (Pons et al. 2002 and Leduc et al. 2006) and soya lecithin containing more than 50 ppm residual protein (Taylor et al. 2009). ELISAs also fail to distinguish certain closely related foods. For example, walnut antisera react with pecan (Niemann et al. 2009) and mustard antisera react to rapeseed (Lee et al. 2008). These may be caused by the presence of cross-reactive epitopes or proteins between two foods (Taylor et al. 2009). Regardless of the above-mentioned limitations, ELISA is still a very powerful tool and remains the method of choice for food allergen detection. ELISA-based food allergen detection methods are developed using either the sandwich ELISA or competitive ELISA format.

Sandwich ELISA

In this assay, as indicated by its self-explanatory name, an allergen of interest is captured between two allergen-specific antibodies. The first allergen-specific antibody is immobilised on the solid phase to capture the allergen, and the second allergen-specific antibody is labelled with enzyme to detect the captured allergen. Allergens need to have enough binding sites, for example, large molecules such as proteins, to allow binding of the two allergen-specific antibodies (Schubert-Ullrich et al. 2009).

Competitive ELISA

This assay is based on the competitive binding of unknown analyte (allergen) in a sample of interest and a known analyte (allergen) to the allergen-specific antibody. The antigen of interest in this case is incubated in the presence of the unlabelled antibody. Antibody/antigen complexes are formed and the solution is then

Table 42.4. Commonly Used Food Allergen Detection Methods

	Principle	Limit of Detection	Advantages/Disadvantages	References
Protein-based methods				
Rocket immunoelec-trophoresis (RIE)	Binding of allergen to human IgE or antibodies raised in animal followed by observation in gel	2.5 mg/kg	Not widely used due to the laborious procedure. Semi-quantitative.	Besler et al. 2002b
EAST inhibition	Binding of specific IgE antibodies to food allergens bound to a solid phase followed by measurement	1 mg/kg	Mainly used for clinical diagnosis. Limited commercial products available due to reliance on human sera. Quantitative.	Nordlee and Taylor 1995
SDS-PAGE and immunoblotting	Proteins are denatured and separated according to their molecular mass. The proteins are then transferred onto a membrane and detected with labelled human IgE or antibody raised in animals.	5 mg/kg	Complex and time-consuming procedure. Reliance on human sera.	Scheibe et al. 2001
Dot immunoblotting	Reaction between sample protein extracts and enzyme-labelled specific antibodies on a nitrocellulose membrane.	Intensity of dot is proportional to the amount of allergen.	Semi-quantitative but simple and inexpensive.	Blais and Phillippe 2000
ELISA	Detects allergens by colourimetric reaction formed by the binding of allergen and specific enzyme-labelled antibody.	0.05–10 mg/kg	Most widely used method. High specificity and sensitivity. Rapid ELISA kits for major allergens are commercially available.	Schubert-Ullrich et al. 2009
Flow-through Microarray	Immobilised allergen specific antibodies on a microarray chip react with allergens.	1.3 ng/mL for ovalbumin	Powerful tool but still in infancy stage for food allergen detection.	Shriver-Lake et al. 2004
Optical biosensors, e.g., surface plasmon resonance (SPR)	Interaction of immobilised molecules (e.g. allergen-specific antibodies) on a sensor surface and a target molecule (e.g. allergens) in solution.	1–12.5 mg/kg	Interaction is measured by either a resonance angle or refractive index value. No need to use labelled molecules.	Yman et al. 2006
DNA-based methods				
PCR with gel electrophoresis	Amplification of a specific DNA fragment followed by agarose gel electrophoresis and visualisation by staining or southern blotting.	<10 mg/kg	Qualitative. Target DNA is less affected than protein during processing and extraction from food matrices. Results do not truly represent actual allergen exposure.	Poms et al. 2001
Real-time PCR	Uses a target-specific oligonucleotide probe with a reporter dye and a quencher dye attached.	<10mg/kg	Requires costly laboratory equipments. Allows for gel-free detection. RT-PCR kits are available for various food allergens.	Oliver and Vieths 2004
DNA-ELISA	Amplified product of specific DNA fragment is linked with a specific protein labelled DNA probe coupled with a specific enzyme-labelled antibody.	<10mg/kg	Semi-quantitative.	Poms et al. 2004

Table 42.5. Examples of Some Commercially Available Test Kits for Food Allergen Detection

Allergenic Food	Target Allergens	Test Format and LOD (mg/kg food)	Testing Time (min)	Manufacturer
Milk	Milk protein	ELISA (<5)	30	Neogen
	Casein	ELISA (0.5)	30	R-Biopharm
	β-Lactoglobulin	ELISA (0.1)	45	ELISA Systems
Eggs	Egg-white protein	ELISA (0.6)	35	R-Biopharm
	Egg-white protein	LFA (LOD: not specified)	<10	Tepnel BioSystems
	Egg protein	ELISA (<5)	30	Neogen
Peanuts	Peanut protein	LFA (<5)	10	Neogen
	Peanut protein	LFA (1)	<10	Tepnel BioSystems
	Ara h1	LFA (5)	10	R-Biopharm
Nuts	Almond protein	LFA (1)	<10	Tepnel BioSystems
	Hazelnut protein	LFA (5)	10	R-Biopharm
Soya beans	Soya protein	ELISA (<5)	30	Neogen
Crustacean	Tropomyosin	ELISA (1)	60	ELISA Systems
Cereals	Gliadin, secalins, hordeins	ELISA (2)	30	R-Biopharm
	Gluten	Dipstick (10–20)	<15	Hallmark
	Gliadin	LFA (2.5)	5	R-Biopharm
Molluscs	Not specified	LFA (5)	<10	Tepnel BioSystems

LOD, limit of detection; ppm, milligram of allergenic food/kg of target food sample.

added to an antigen-coated well followed by washing to remove any unbound material. The higher the concentration of antigen in the sample, the lower will be the amount of free antibody able to bind to the antigen in the well. The allergen concentration in the sample in this assay is therefore inversely proportional to OD values obtained after adding the substrate. Competitive ELISA assay is known for its ability to detect relatively small proteins (Poms et al. 2004). Today, continuous developments in technology allows the possibility of enzyme labelling of either the analyte or the analyte-specific antibody.

LFA and Dipstick Tests

Both of these tests are modified versions of ELISA and are designed to meet the growing need of portable, reliable, user friendly and cost-effective methods that can detect trace amount of allergens in suspected foods within a short period of time (Schubert-Ullrich et al. 2009). Although quantification is possible in principle by using special strip test readers, commercially available LFA and dipstick test are primarily intended for qualitative or semi-quantitative purposes (yes or no). Table 42.5 shows some of the commercially available tests based on ELISA, LFA and dipstick methods.

LFAs or strip tests are immunochromatographic tests with a mobile phase that allows movement of the allergen–antibody complex and/or the sample along a test strip. This technique is based on an immunochromatographic procedure that utilises antigen–antibody properties and enables rapid detection of the analyte (Rong-Hwa et al. 2010). For LFAs using a sandwich ELISA, an allergen-specific detection antibody, deposited on the membrane, is solubilised upon introduction of a liquid sample and moves along with the sample until it reaches the zone where

a capture antibody has been immobilised. At that point, the allergen–antibody complex is trapped. The presence or absence of allergen is determined with the colour development pattern. Competitive ELISA format can also be applied in LFA tests. LFAs results can be obtained within 3–15 minutes after running the assay (Schubert-Ullrich et al. 2009).

Dipstick tests are also based on a similar principal as LFA but with no mobile phase. Instead, an incubation phase is required in the dipstick test. Oliver et al. (2002) used dipstick assay to detect peanut and hazelnut allergens and reported that results of the dipstick assays and the corresponding ELISA were in concordance. Although most dipstick tests are based on sandwich ELISA format, application of competitive ELISA has been reported. Depending on the time needed for incubation, food allergen detection time, using dipstick test, could vary from 10 minutes to 3 hours (Schubert-Ullrich et al. 2009).

PROTEOMIC APPROACH

Recently, proteomics has gained much attention especially for the detection and identification of IgE-binding allergens in complex mixtures. Proteomics is useful for identification and characterisation of proteins, including their post-translational modifications, protein conformations (native, denatured, folding intermediates) and protein–protein interactions (Leadbeater and Ward 1987, Alomirah et al. 2000).

A proteomic analysis usually consists of sample collection and preparation, protein separation using electrophoresis or chromatography and protein identification and characterisation using mass spectrometry. Successful identification of proteins depends on many factors such as the sensitivity of the mass spectrometer, the completeness of the database, post-translational

modifications and more (Monaci et al. 2006). Many technologies, including protein separation via two-dimensional electrophoresis or liquid chromatography (LC), mass spectrometry and arrays (to map protein–protein interactions), are applied in proteomic-based studies. Shefcheck and Musser (2004) showed useful application of LC-based proteins separation with MS analysis (LC-MS/MS) to detect peanut allergen Ara h1 in ice cream with a detection level of 10 mg/kg. Proteomic studies can offer more detailed information about allergens (Shefcheck and Musser 2004), help in the identification of new allergens (Yu et al. 2003) and provide objective evaluation of changes induced by genetic modification (Herman et al. 2003). However, the requirement of a highly skilled operator, the high cost of mass spectrometers, the length of time required for sample preparation and analysis, and the need for separate protocols and optimisation for each sample prevent current proteomic approaches to be used for routine detection of food allergens. Nevertheless, proteomics remains a promising tool in allergen studies due to its great potential for detection and identification of food allergens in complex mixtures. Recent developments in mass spectrometer instrumentation and software offer ultra-high throughput, high sensitivity, and high-resolution capabilities (Chassaigne et al. 2009). Currently, attempts to couple more efficient protein separation (microfluidic) and detection technologies with MS analysis are progressing. Proteomic approaches could therefore soon be widely applicable for detection and identification of food allergens.

DNA-Based Allergen Detection Methods

Detection of allergens in food, by traditional protein-based detection methods, can sometimes be very difficult, as they are often present in minute amounts and are masked by the food matrix (Keck-Gassenmeier et al. 1999). DNA-based allergen detection methods have emerged as an alternative and complementary method to detect allergens where effective protein-based allergen detection methods are unavailable. DNA-based tests also possess high accuracy and sensitivity and, in general, are able to withstand harsh processing conditions better than corresponding allergenic proteins (Mustorp et al. 2008). On the other hand, in some food, DNA are partially or totally degraded and consequently false-negative results could occur, while the food may still contain the allergen. In addition, some food matrix components may reduce DNA amplification efficiency. DNA-based methods, in comparison to ELISA-based methods, are relatively more complicated, require more equipment and have lengthier protocols. For this reason, DNA-based methods have been considered impractical for routine detection. They may, however, be desirable for use by regulatory agencies and in institutions where there is easy access to appropriate equipment.

The sensitivity of the DNA-based methods strongly depends on the amount and on the quality of the template DNA since the DNA encoding the allergen in the food samples may be present in low amounts and may also be degraded as a result of processing (Holzhauser et al. 2006). Three DNA-based approaches are currently available to detect food allergens.

Polymerase Chain Reaction (PCR) with Gel Electrophoresis

The assay involves DNA extraction from food, amplification of specific DNA fragment using primers that bind selectively to complementary parts of the DNA to be amplified, followed by agarose gel electrophoresis (Besler 2001). PCR consists of three steps, determined by different temperatures in every cycle of amplification: denaturation of double strands DNA, annealing of the primers and extension of the primers by the enzyme Taq polymerase (Poms et al. 2004). The amplified product is loaded to run agarose gel electrophoresis and visualised by staining the gel. PCR with gel electrophoresis approach is good for qualitative detection of allergen in the food.

PCR with ELISA

This assay is a combination of a highly specific DNA-based method with the relatively simple and highly sensitive ELISA assay for semi-quantitative analysis (Poms et al. 2004). As in other PCR-based methods, extraction and purification of DNA from a food sample and amplification of specific DNA fragment encoding to suspected allergen using primers in a thermocycler are prerequisite for PCR-ELISA assay. The ELISA component of the test involves immobilisation of the amplified PCR product on a solid phase (a microplate), denaturation of double strand, hybridisation with specific probe, detection of the probe with enzyme-conjugated antibody and observation of the enzymatic colour reaction after addition of substrate (Holzhauser et al. 2002). The DNA concentration can be determined via absorbance obtained from an enzyme–substrate reaction.

Real-Time PCR

Real-time PCR allows gel-free detection 'in real time' with high accuracy by using a target-specific oligonucleotide probe with a reporter dye and a quencher dye attached (Desjardin et al. 1998). Oliver and Vieths (2004) reported real-time PCR method to be as sensitive as sandwich ELISA in detecting peanut allergens in 33 food samples. Many different types of real-time PCR assay kits are commercially available to detect many of the priority food allergens (Poms et al. 2004), including kits for detecting allergen encoding genes from mustard, sesame and celery (Mustorp et al. 2008).

CONCLUSION

Food allergy will likely continue to be an important food safety issue in the coming decades. Although substantial progress has been made in the field in the last 20 years, much still remains unknown. One area still requiring significant work is the question of the minimum eliciting dose required to provoke reactions in sensitised individuals. Increasing prevalence rates along with the possibility of severe allergic reactions after exposure to very low level of allergens in sensitised consumers continue to be a concern. Although exact threshold doses for food allergens are not known at present, levels of detection offered by current

commercial allergens detection kits appear to be adequate for allergic consumer protection. There continues to be a need, however, for more sensitive and easily applicable analytical methods and improved understanding of the sources of cross-contact along the food value chain.

Currently, ELISA-based rapid allergens detection kits including LFA and dipstick are extensively used to detect suspected major allergens in processed foods. They will likely remain the method of choice in the food industry for a while, because of their fast and easy usage. Other methods such as surface plasmon resonance on automated platforms or protein microarrays in combination with immunochemical analytical approaches can provide rapid, efficient and simultaneous detection of multiple allergens in multiple samples (Moreno-Bondi et al. 2003 and Schubert-Ullrich et al. 2009). However, application of these novel techniques to food allergen analyses is still limited and will hopefully grow. Similarly, use of proteomics approach to identify and detect food allergens is expected to increase as microfluidic system-based protein separation and analysis systems become available as handheld devices in the near future. It is also anticipated that DNA-based food allergen detection methods will continue to be used as a valuable reinforcement tool in the ongoing effort to manage food allergens in the food supply.

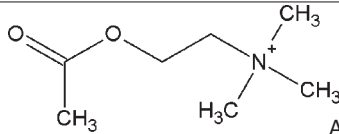
Biogenic Amines in Foods

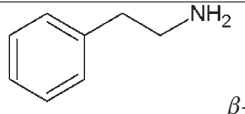
Angelina O. Danquah, Soottawat Benjakul, and Benjamin K. Simpson

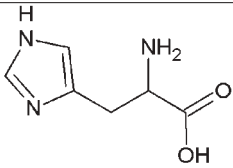
Abstract: Biogenic amines (also known as biologically active amines) are low-molecular weight organic compounds produced in biological systems by enzymatic decarboxylation of certain amino acids such as histamine and tyrosine. Examples include dopamine, histamine, norepinephrine, serotonin, and tyramine. They function in the body as neurotransmitters and relay signals between neurons across synapses to impact on mental functions, blood pressure, body temperature, appetite, and several other physiological processes. The levels of biogenic amines in the body are regulated for proper functioning of the various physiological processes that they
are associated with. Certain foods contain biogenic amines that can add to the amounts naturally present in the body. High intake of these foods could upset the balance of biogenic amines in the body to cause health problems such as hypotension, hypertension, gastrointestinal distress, headaches and migraine, and others. Thus, it is crucial to curtail the formation and levels of these compounds in certain food products. This chapter discusses the formation and occurrence of biogenic amines in selected food products, their effects of human health and significance to the food industry, their detection, and their fate during processing and storage. The chapter also covers regulation of biogenic amines in foods.

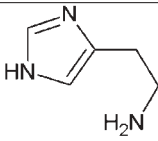
INTRODUCTION

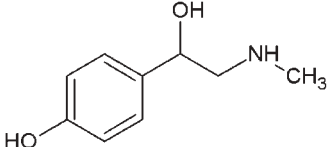
Biogenic amines, also known as biologically active amines, are nitrogen-containing low-molecular weight organic compounds that are naturally present in food products such as cheese, wine, beer, plant food, fish, and meat (Tarjan and Janossy 1978). These substances are described as biogenic because they are formed by the action of living organisms. In foodstuffs, they are perceived as undesirable anti-nutritional factors of public health concern since they have been associated with food poisoning (Shalaby 1996), particularly when ingested in large quantities, or where there is inhibition of their breakdown in humans. Examples of biogenic amines are the catecholamines and indoleamines. The prominent ones include acetylcholine (ACh), histamine, tyramine, dopamine (Fig. 43.1), serotonin (Fig. 43.2), norepinephrine (NE; also known as noradrenalin (NA)), and epinephrine (or adrenalin; Fig. 43.3).

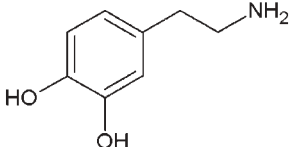
Acetylcholine, also known as 2-acetoxy-*N,N,N*-trimethylethanaminium, is a neuromodulator found in both the peripheral and the central nervous systems (PNS and CNS). The compound has a chemical formula of $CH_3COOCH_2CH_2N^+(CH_3)_3$ and is formed from the esterification of choline with acetic acid in a reaction catalyzed by


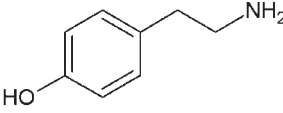


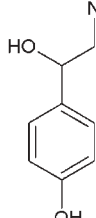


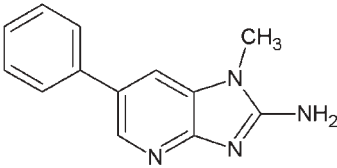


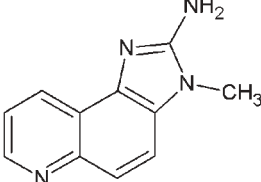


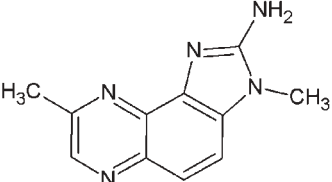


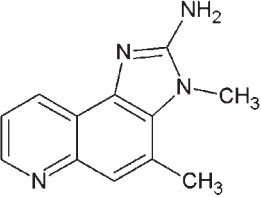












---

the enzyme choline acetyl transferase. In the PNS, ACh acts to activate muscles, while in the CNS, it elicits excitatory actions.

Histamine is derived from the amino acid histidine via decarboxylation by histidine decarboxylase. It is a neurotransmitter and is produced by basophiles and mast cells, and functions in immune response and the regulation of physiological functions in the gut (Marieb 2001). Histamine enhances the permeability

of capillaries to white blood cells and protein antibodies, which are needed to destroy foreign substances and nullify their harmful effects. It also acts in pro-inflammatory response to tissue damage or allergic reactions and also enhances the secretion of gastric HCl through histamine receptors.

Tyramine is formed from the amino acid tyrosine by decarboxylation, and it occurs in many common foods that humans

Figure 43.3. Scheme for the synthesis of adrenaline (epinephrine) from tyrosine.

ingest or consume. Well-known food sources of tyramine include fermented, pickled and aged foods, marinated foods, smoked foods, chocolate, alcoholic beverages, and spoiled foods. Its production and accumulation in the body have been linked to elevated blood pressure and headaches.

Serotonin, known systematically as 5-hydroxytryptamine, is synthesized from L-tryptophan by a series of reactions (Fig. 43.2), including hydroxylation, decarboxylation, and deamination steps. These reactions involve the participation of several enzymes, including tryptophan hydroxylase (TPH), 5-hydroxytryptophan decarboxylase, and monoamine oxidase (MAO). Serotonin is a neurotransmitter found mostly in the gastrointestinal tract (GIT), the CNS, and platelets of animals including humans. In the GIT, serotonin acts to regulate intestinal movements; in the CNS, serotonin performs various functions, including the regulation of appetite, mood, and sleep, as well as muscle contraction and some cognitive functions

(Berger et al. 2009). Platelet-related serotonin is involved in haemostasis and liver regeneration (Lesurtel et al. 2006). In plants, serotonin is thought to be produced as a mechanism for obviating the build-up of toxic ammonia. This involves the coupling of NH_3 to the indole of L-tryptophan followed by decarboxylation into tryptamine and subsequently by cytochrome P450 (Cyt P_{450}) monooxygenase-mediated hydroxylation to serotonin. Plant sources of serotonin include mushroom, tomato, plantain, banana, plum, kiwifruit, walnut, and hickory. Excessive levels of serotonin can be toxic to humans and is manifested by specific cognitive, autonomic, and somatic effects that may range from nondetectable to fatal (Boyer and Shannon 2005).

Tryptamines are a group of alkaloid compounds found in plants, animals, and fungi. Well-known tryptamines include serotonin and melatonin. These compounds are known for their psychotropic effects and this forms the basis of their use by some people; examples include psilocybin (from "magic mushrooms")

and dimethyltryptamine (Jones 1983). There are also synthetic counterparts of tryptamines, and these include the drug suma-triptan and its derivatives used to treat migraines (Yen and Hsieh 1991).

NE or NA is synthesized in the adrenal medulla and the neurons of the sympathetic nervous system from tyrosine via several enzyme-catalyzed reactions including hydroxylation followed by decarboxylation to dopamine and a final oxidation step. The enzymes involved in the reactions are tyrosine hydroxylase, DOPA decarboxylase, and dopamine β-hydroxylase, respectively (Aston-Jones et al. 2002). The NE (or NA) compound serves multifunctions, as a stress hormone, a neurotransmitter, and as a drug. As stress hormone, it is involved in triggering responses such as increasing heart rate, facilitating release of glucose from storage depots, and increasing blood flow to the skeletal muscle; as a neurotransmitter, it is released in the brain to mitigate inflammations; and as a drug, it can increase vascular tone and blood pressure.

Epinephrine or adrenaline is synthesized in the adrenal gland from the amino acids phenylalanine and tyrosine via a series of intermediates (Fig. 43.3). In the first step, tyrosine is oxidized to L-DOPA, followed by decarboxylation to dopamine, which is subsequently oxidized to NE and then methylated to form adrenaline or epinephrine. It functions both as a hormone and as a neurotransmitter and carries out manifold functions in the body. For instance, it increases heart rate, modulates dilation of blood vessels and air passages, and participates in the fight/flight response of the sympathetic nervous system. It also participates in the contraction of the smooth muscles; inhibits insulin secretion while enhancing glucagon secretion in the pancreas; and also stimulates glycolysis in the muscle, lipolysis in adipose tissues, and glycogenolysis in the liver and the muscle (Cannon 1929).

Dopamine, also known as 4,2-aminoethyl benzene-1,2-diol, has a molecular formula of $C_6H_3(OH)_2(CH_2)_2NH_3$. It is synthesized by nervous tissues and the adrenal medulla from tyrosine (L-Tyr) by hydroxylation to form dihydroxyphenyl alanine (L-DOPA) in a reaction catalyzed by tyrosine hydroxylase, followed by a decarboxylation step catalyzed by DOPA decarboxylase (Fig. 43.3). Dopamine thus formed may be processed further into NE by the enzyme dopamine β-hydroxylase and then methylated into epinephrine (Fig. 43.3). Dopamine is involved in motivation, addictions, behavioral manifestations, and coordination of bodily movements (Yen and Hsieh 1991).

Other commonly known biogenic amines and their precursors include cadaverine, agmatine, β-phenylethylamine, and putrescine derived, respectively, from lysine, arginine, phenylalanine, and ornithine. Polymerization of putrescine forms the polyamines spermine and spermidine (Pegg and McCann 1982). These polymeric products are highly resistant to degradation during processing and are capable of withstanding procedures like canning, freezing, smoking, and cooking (Etkind and Wilson 1987). Some biogenic amines are present at low levels in fresh foods; however, these levels may increase via microbial decarboxylation of free amino acids during processes such as fermentation, storage, and in food spoilage. Various factors such as pH, temperature, salt concentration, and glucose availability all influence the formation of biogenic amines in foodstuffs.

The importance of biogenic amines to the food industry is due to two main reasons. First, if ingested in high quantities, they may induce toxic effects. For example, consumption of tyramine and histamine has been associated with disorders such as a burning sensation in the throat, flushing, headaches, nausea, hypertension, numbing and tingling of the lips, rapid pulse, and vomiting (De Vries 1996). Certain biogenic amines have also been implicated in the formation of carcinogenic nitrosamines, and the variation in biogenic amine levels has been suggested as a useful chemical indicator of food quality or spoilage. Thus, the food industry has developed several techniques for determining biogenic amine concentrations in food products for various purposes, including research, health and safety, or quality control. The effects of food processing on biogenic amine formation or levels have also been extensively studied in order to develop methods of limiting biogenic amine formation in food products (Stratton et al. 1991, Shalaby 1996). Because of its potential health concerns, governments and related regulatory agencies have established legal limits and recommendations for these compounds in certain products (FDA 2001).

BASIC STRUCTURE AND FORMATION

Biogenic amines may be classified into three main groups based on their molecular structures as aliphatic, aromatic, and heterocyclic. Examples of aliphatic biogenic amines include methylamine, dimethyl amine, ethylamine, diethyl amine, butyl amine, cadaverine, putrescine, spermidine, and spermine; examples of the aromatic amines are tyramine, octapamine, dopamine, and synephrine; and examples of the heterocyclic biogenic amines are 2-amino-2-methylimidazolo[4,5-f]quinolone (IQ), 2-amino-3,8-dimethylimidazo[4,5-f]quinoxaline and 2-amino-1-methyl-6-phenylimidazo[4,5-b]pyridine (Fig. 43.1).

Biogenic amines may be formed endogenously during normal metabolic processes in living cells from the degradation of biological molecules like proteins and/or decarboxylation of certain amino acids (e.g., tyrosine, phenylalanine, arginine, and histidine) by microbial enzymes. Endogenous amines formed from cellular metabolism play a plethora of important roles within the cardiovascular, nervous, and digestive systems. They are produced in many different tissues, for example, adrenaline is produced in the adrenal medulla, while histamine is formed in mast cells and liver and is subsequently transmitted locally or via the blood stream to perform various functions as in the modulation of growth and proliferation of eukaryotic cells by spermine and spermidine (Pegg and McCann 1982). Biogenic amines may also be formed exogenously as intermediates in the chemical and pharmaceutical industries, or released into the atmosphere from livestock breeding operations, animal feeds, waste treatment/incineration, and in automobile exhaust fumes. The exogenous biogenic amines are directly absorbed in the intestine, a process that is enhanced by intake of alcohol.

The amino acid decarboxylase enzymes of microorganisms carry out the dual functions of producing the biogenic amines for normal functions in the organism or removing the substrate (parent amino acid) to prevent the excessive accumulation of these substrate molecules. Several of the decarboxylase enzymes

act on the α-carboxyl group of the appropriate L-amino acid to produce the corresponding biogenic amine and carbon dioxide. The enzymatic decarboxylation process depends on various factors such as the availability of the substrate in free form, the presence of decarboxylase-producing microorganisms, and the reaction medium conditions. The amino acid substrates for the decarboxylations are either naturally present in the food material or produced via proteolysis by endogenous proteases in the raw material. Also, decarboxylase enzyme-producing microorganisms may be present as part of the natural micro flora of a food product, and they may be introduced by contamination or added as part of a starter culture. Medium conditions that favor the growth of the bacteria (i.e., carbon source, pH, temperature, availability of O_2, and light) and production of the decarboxylase enzymes in active forms all promote the formation of biogenic amines.

Biogenic amines may also be broken down by the MAO enzyme system to control the levels of these compounds. Proteolysis to form free amino acids may also be potentiated by the action of exogenous proteases that are intentionally added for the modification of foodstuffs.

In foods and the food industry, it is the exogenously formed biogenic amines that are of particular interest. Heterocyclic amines (HCAs) are formed in muscle foods (beef, pork, poultry, and fish) during high temperature cooking procedures such as frying, broiling, and barbecuing. The amino acids from food proteins (meats) condense with creatinine to result in the HCAs. HCAs can be potent mutagens and carcinogens and may increase the risk of cancer for humans (Adamson and Thorgeirsson 1995). Nonetheless, biogenic amines are also used to treat depression and to promote positive mood.

OCCURRENCE IN FOOD PRODUCTS

FERMENTED FOOD SOURCES

Fermentation is a biological method of processing foodstuff to preserve its quality or to transform foods into stable and useful forms. The fermentation process invariably makes finished products with characteristic flavors and textural properties. The process is potentiated mostly by microbial activity and metabolism and by enzymes. Several different microorganisms including *Lactococcus, Lactobacillus, Leuconostoc, Streptococcus,* and *Pediococcus* species have been shown to participate in various food fermentations. These microorganisms may be naturally present in the food material or added to foods as starter culture, and they secrete their enzymes (including various decarboxylases and hydrolases) in foods for their transformation. As a result, certain fermented foods may accumulate large amounts of biogenic amines through the decarboxylation of amino acids by microbial decarboxylases or via proteolysis by proteases to generate intermediates (free amino acids) that may condense with creatinine to form heterocyclic biogenic amines. For example, products such as the Chinese mitten crab, beer, cheese, and other fermented foods have all been shown to accumulate high levels of histamine during storage (Stratton et al. 1991, Izquierdo-Pulido et al. 1999, Xu et al. 2009). Although the presence of biogenic amines may not always indicate spoilage, their presence in food products is not desired due to their potential health effects.

Cheese

Cheese is a commonly consumed fermented food product. During fermentation and ripening of cheeses, milk casein is hydrolyzed by proteases and peptidases into a mixture of smaller peptides and free amino acids. Some of the free amino acids produced become substrates for the decarboxylases of microorganisms associated with cheeses to form biogenic amines (mainly, putrescine, cadaverine, histamine, and tyramine) in the products (ten Brink et al. 1990). As well, free amino acids from proteolysis may form heterocyclic biogenic amines with creatinine.

Some microorganisms have been implicated in the formation of histamine, tyramine, putrescine, and cadaverine in cheeses. For example, *Lactobacillus buchneri* is known to produce vast amounts of histamine in cheeses, which can potentially elicit histamine poisoning in consumers, while *L. brevis* and *Enterococcus faecalis* have also been implicated in the formation of tyramine in certain cheese products (Stratton et al. 1991, Shalaby 1996).

Certain conditions can promote or inhibit the formation of biogenic amines in foods by microbial enzymes. The increase of free amino acids during fermentation is one of the main promoters of biogenic amines formation since the amino acids are the substrates for the enzymatic decarboxylase action, leading to the formation of the amines and carbon dioxide. As a result, cheeses with longer ripening times and higher degrees of proteolysis may have higher amounts of biogenic amines. The use of high temperatures during cheese making and/or storage may also increase biogenic amine levels in the products. When cheeses are stored or transported under different temperature conditions, the products handled under proper refrigeration conditions (4°C) tend to have lower levels of biogenic amines than their counterparts stored or transported at elevated temperatures (e.g., 25°C; Shalaby 1996, Pinho et al. 2001). On the other hand, high-temperature pasteurization of milk prior to its use for cheese-making can curtail biogenic amine formation in the product, and when high-temperature pasteurized milk is used in combination with particular starter cultures, it could result in the formation of considerably lower levels of biogenic amines in the cheese product; the use of appropriate levels of acid and salt may also slow down biogenic amine production in cheese products (Ordóñez et al. 1997, Valsamaki et al. 2000, Martuscelli et al. 2009).

Alcoholic Beverages

Alcoholic beverages, including beer and wines, are produced from plant materials by microbial fermentation process (e.g., red wine is produced by fermentation of grape must) and are common sources of biogenic amines. Beer and red wines have been implicated in outbreaks of histamine and tyramine poisoning. Biogenic amines in alcohol act synergistically to elicit various adverse health symptoms such as nausea, respiratory

problems, palpitations, headaches, rashes, and blood pressure problems (Bodemer et al. 1999, Du Toit 2005). In the process, fermentation microorganisms such as *Saccharomyces cerevisiae* and *S. ellipsoideus* hydrolyze carbohydrates into simpler sugars that are further degraded into ethanol and a variety of flavor compounds. The beverages are then stored and aged for various time periods. In wines, the most common biogenic amines are histamine, tyramine, and putrescine, which are formed by bacterial strains such as *Pediococcus spp., L. brevis, L. buchneri, Leuconostoc mesenteroides*, and *Oenococcus oeni* (Guerrini et al. 2002, Moreno-Arribas et al. 2003).

The production of beer entails an initial mashing step to produce the wort, which is subsequently inoculated with yeast (e.g., *S. carlsbergensis* or *S. cerevisiae*) to potentiate the fermentation. Histamine, tyramine, putrescine, and cadaverine have been found in certain beers and because alcohol enhances the absorption of biogenic amines in humans, a legal upper limit for biogenic amine content of 2 mg per alcoholic beverage has been established as guide for manufacturers of the products (Moreno-Arribas et al. 2003).

The formation and accumulation of biogenic amines in beer is due to several factors, such as the quality of the raw material and microbial contaminations. Thus, lactic acid bacteria form putrescine, cadaverine, histamine, and tyramine during fermentations; storage and aging may lead to further increases in the levels of these compounds in the food products (Tabor et al. 1958, Bodemer et al. 1999).

The formation and/or accumulation of biogenic amines in foods may be controlled by adopting proper good sanitary and hygienic practices during food handling and processing, to control microbial contaminations and prevent temperature abuse during storage and transportation.

Meat Products

Fermentation is also used as a traditional preservation method to extend the shelf life of meat. Examples of fermented meats include ham, salami, pepperoni, chorizo, thuringer, bologna, and cervelat (Potter and Hotchkiss 1998). Sausages are classified as semi-dry and dry sausages, based on fermentation techniques. The semi-dry sausages are characterized by a relatively higher water activity ($A_w = 0.90$–0.94) and a relatively higher pH (≤5.0), as opposed to A_w of 0.85–0.91 and a pH of ≤ 4.5 for dry sausage. The semi-dry sausages are usually produced using a lactic acid bacteria starter culture over a relatively shorter fermentation period, while dry sausages are fermented over much longer time periods using the endogenous microflora associated with the raw material. The biogenic amines histamine, tyramine, tryptamine, cadaverine, putrescine, 2-phenylethyamine, spermidine, and spermine have all been found in dry sausages. However, their levels and distribution vary depending on factors such as quality of the raw material and the availability of precursor molecules to serve as substrates (Santos 1996, Suzzi and Gardini 2003).

Raw meats tend to have lower amounts of biogenic amines such as spermine and spermidine unlike fermented products, and some industry-derived commercial products tend to have rela-

tively higher amounts of biogenic amines than their nonindustry-produced traditional products (Lakritz et al. 1975). The microorganisms responsible for biogenic amines production in fermented meats include *Enterobacteriaceae*, *Enterococci*, *Lactobacilli, Pediococcus,* and *Pseudomonads*. The lactic acid bacteria strain, *Lactobacilli* and *Enterococci,* are more associated with tyramine production, while *Enterobacteriaceae* is more connected with high putrescine and cadaverine levels in fermented meat products (Suzzi and Gardini 2003).

It is possible to have the microbial load associated with fermented meat products to be low; however, the enzymes (proteases and decarboxlases) released by microorganisms into the products may survive the fermentation process and cause continued production of biogenic amines in the finished products. Storage of the raw materials intended for fermentation at low temperatures is a good practice to control both microbial proliferation and enzymatic activity that lead to biogenic amines formation in the products. Fermented meat products made from raw material that have been exposed to high temperatures tend to have significantly high contents of biogenic amines such as tyramine, cadaverine, and putrescine.

In general, high temperature, high pH, and low salt content can enhance biogenic amine formation. Higher temperatures favor proteolytic, lipolytic, and decarboxylation reactions. For instance, the amount of biogenic amine content is higher in products prepared at 15°C compared with similar products made at 4°C, and more histamine is formed during ripening at 18°C as compared with processing at 7°C; biogenic amine formation is also less at lower pHs, because the decarboxylation of histidine tends to be relatively low at acidic pH (Maijala et al. 1995). Thus, amine-negative lactic acid bacteria are preferred as starter culture to rapidly produce acids to decrease the pH in the product(s) and suppress biogenic amine formation (Battcock and Azam-Ali 1998). A high salt content also generally inhibits microflora growth because the reduced water activity makes the product less conducive for the growth and proliferation of microbes; consequently, low levels of biogenic amine are formed.

Other factors may also contribute to the biogenic amine accumulation. For example, bacteria growth and metabolism are enhanced by the presence of glucose, while the addition of sulphites or nitrites suppresses the formation of cadaverine, putrescine, and cadaverine. In the case of sausages, the diameter of the product may affect biogenic amine formation, because it impacts the salt content and water activity of the product. Thus, sausages with bigger diameters tend to have greater tendency for biogenic amine production and accumulation than smaller-sized sausages (Battcock and Azam-Ali 1998).

In addition to meats, fish are also fermented into products such as faseekh, fish paste (e.g., bagoong, patis, and shrimp paste), and fish sauce (e.g., joetgal, shottsuru, garum, nuoc mam, and nam pla). Like their meat counterparts, these products also may contain biogenic amines. Histamine, putrescine, cadaverine, tyramine, spermidine, and spermine have all been detected in fermented fish products and their levels increased with storage (Mah et al. 2002). However, the amounts of biogenic amines found in these products (0–70 mg/kg sample) are considered as

safe for human consumption, if they are handled and stored properly.

Vegetable Products

Vegetables may also be fermented to preserve them or form modified products with characteristic flavors and textures. Fermented vegetable products include pickles, ripe olives, sauerkraut, doenjang, shoyu, stinky tofu, miso, tempeh, injera, kimchi, koji, natto, soy sauce, brandy, cider, sake, and vinegar; they are produced from sources such as beans, grains, cucumbers, lettuce, olives, cabbage, turnips, fruits, and rice. In general, biogenic amine content is very low in fresh vegetables; however, the concentration increases during the fermentations process and throughout storage. Sauerkraut is made from shredded cabbage by fermentation with lactic acid bacteria. In the case of fermented vegetable products, there does not appear to be a significant correlation between biogenic amine levels and spoilage unlike the situation with fermented meat products, and compounds like tyramine, putrescine, and cadaverine are commonly found in fermented vegetable products (Potter and Hotchkiss 1998, Kalac et al. 1999, 2000a, 2000b).

The amounts of biogenic amines present in fermented vegetable products also vary and depend on factors such as temperature, salt content, and pH/acidity, as well as starter culture type. These factors all affect the growth and metabolism of the organism, which influence the formation of the biogenic amines. Low temperatures generally minimize microbial growth and proliferation, and enzyme activities to reduce biogenic amine formation, while elevated temperatures tend to do the reverse.

Salt plays an important role in the fermentation of vegetables. By modulating the A_w levels, salting can influence the texture of fermented vegetable products. For example, under dry salted fermentation conditions, product firmness is enhanced with increasing salt content. Although a high salt may suppress the activity of certain (desirable) bacteria, there are halophilic bacteria that are salt tolerant, and advantage may be taken of this fact to use halophilic bacteria such as *Enterococci* to overcome the growth and proliferation of a moderately salt tolerant *Lactobacilli* species in fermented vegetable products (Kalac et al. 1999).

Acidity and pH are also important in the fermentation of vegetables. Hitherto, the use of starter cultures helps to exclude undesirable microorganisms by generating an acidic milieu that is not conducive for the growth of certain microorganisms. Thus, the pH level in a product can determine the types of microorganisms that would be dominant in the course of the fermentation process. For instance, *Lactobacillus* and *Streptococcus* species are acid tolerant, and when they are used in mixed cultures, species like *Leuconostoc mesenteroides* would initiate the process and produce an acidic environment, and then be replaced by *L. plantarum* till the lactic acid level rises sufficiently to kill the *L. plantarum* and be replaced by *L. pentoaceticus*. *L. plantarum* is a typical tyramine producer; thus, products formed with such cultures would be expected to accumulate biogenic amines (Battcock and Azam-Ali 1998, Suzzi and Gardini 2003).

Fermented vegetable products also accumulate biogenic amines during storage. For example, the levels of tyramine and putrescine in sauerkraut increase during storage, and the longer the storage period, the more of these biogenic amines accumulate (Kalac et al. 2000a, 2000b).

Non-fermented Foods

Biogenic amines occur in non-fermented foods also. Fresh fish and meats in particular are known to contain biogenic amines due to their high protein and free amino acid contents and their high perishability. These food products have also been associated with histamine poisoning, which also attests to the presence of these compounds. Biogenic amines in non-fermented foods are also formed by the action of decarboxylating and proteolytic enzymes exuded by microorganisms naturally present as part of the native microbial flora of fish and meats, or microorganisms purposefully added as starter culture, or added through contamination. High levels of biogenic amines in foodstuffs may be used as indices of undesirable microbial growth and spoilage.

Fish

Biogenic amines in fish are of particular health concern because they cause histamine poisoning in humans (Sanchez-Guerrero et al. 1997). Histamine poisoning or scombroid fish poisoning (scombrotoxicosis) is the most widespread form of seafood poisoning in fish-producing and fish-consuming communities. Fish in the *Scombridae* and *Scomberesocidae* families as well as non-scombroid fish have both been implicated in biogenic amine poisoning of humans. These include fish species like bluefish (*Pomatomus* spp.), bonito (*Sarda* spp.), mackerel (*Scomber* spp.), mahi mahi (*Coryphaena* spp.), marlin (*Makaira* spp.), pilchards (*Sardina pilchardus*), sardines (*Sardinella* spp.), saury (*Cololabis saida*), sockeye salmon (*Oncorhynchus nerka*), tuna (*Thunnus* spp.), and yellowtail (*Seriola lalandii*) (Lehane and Olley 2000, Sarkadi 2009). These fish species tend to have high levels of free histidine in their tissues, which may undergo decarboxylation to form the toxic histamine. The levels of biogenic amines in fish tissues vary greatly and are influenced by various factors including muscle type, the native microflora, harvesting, and postharvest management practices (including handling, processing, transportation and storage; Veciana-Nogues et al. 1997a, 1997b, Gloria et al. 1999).

Of the biogenic amines found in fish tissues, histamine usually tends to be the most abundant, followed by putrescine and cadaverine in that order. For example, tuna fish samples stored at 20°C produced histamine, cadaverine, and putrescine levels of 3103 μg/g, 44.2 μg/g, and 3.0 μg/g, respectively, after 48 hours of storage (Veciana-Nogues et al. 1997a, 1997b). Nonetheless, these biogenic amines may not occur in all fish tissues, as is the case for tyramine, which is absent in sea bream (*Sparus aurata*) but present in anchovies (*Engraulis mordax*; Koutsoumanis et al. 1999).

The relative amounts of biogenic amines and their distribution in fish tissues depend to a large extent on the types of microorganisms associated with the raw material and their capacity to

produce decarboxylases and hydrolytic enzymes like proteases and lipases. Generally, when the microbial load is high, the biogenic amine levels also tend to be high (Du et al. 2002).

Approximately, one-third of the microorganisms isolated from spoiled tuna and mackerel are decarboxylase enzyme producers. These include *Acinetobacter iwoffi, Aeromonas hydrophila, Clostridium perfringens, Enterobacter aerogenes, Hafnia alvei, Morganella morganii, Proteus mirabilis, Proteus vulgaris, Pseudomonas fluorescens, Pseudomonas putrefaciens,* and *Vibrio alginolyticus,* and they are members from both mesophilic and psychrophilic organisms. In this regard, the mesophilic types tend to play a relatively more significant role in histamine production and fish flesh deterioration than their psychrophilic counterparts, and species like *Morganella morganii*, as well as *Enterobacteriaceae, Clostridium,* and *Lactobacillus* are of particular importance in terms of histamine production in fish (Omura et al. 1978, Taylor 1986, Middlebrooks et al. 1988, Lakshmanan et al. 2002, Kim et al. 2006).

Environmental factors (e.g., temperature, pH, and salt content) also play a role in biogenic amines formation and accumulation in fish tissues, and these factors may be manipulated to slow down biogenic amine formation.

Fish muscle type also influences the amounts of biogenic amines that form and/or accumulate in fish tissues. In this connection, red-fleshed fish tend to have higher levels of histamine in their tissues than their white-fleshed counterparts. This is due to the relatively higher content of the precursor molecule, histidine, in red-fleshed fish tissues, as well as higher amounts of carbohydrates and lipids, and a slightly more acidic environment, all conditions that favor the growth and proliferation of decarboxylase positive microorganisms.

The importance of temperature as a foremost manipulative factor to limit the formation of biogenic amines in fish tissues is due to the fact that several of the major histidine-decarboxylase-positive bacteria associated with fish are mesophilic. Thus, a decrease in temperature slows down their growth and metabolism (Ababouch et al. 1991). For example, icing decreases the initial mesophilic microorganism population while increasing the lag phase of growth. Nevertheless, decreasing product temperature is not an absolute means of control. This is because certain psychrophilic bacteria can also produce decarboxylases that can lead to the formation of biogenic amines, even at proper refrigeration temperatures. Furthermore, the decarboxylase enzymes released in fish tissues are still functional at low temperatures although at a reduced rate. Thus, proper postharvest fish management is crucial to control formation and accumulation of biogenic amines in fish flesh.

Meat

Fresh meats (beef, pork, and poultry) are also non-fermented foods known to have biogenic amines. Their high proteinaceous nature makes them prone to proteolysis to form free amino acids that may subsequently be decarboxylated by microbial enzymes into the biogenic amines. Spermine and spermidine are believed to be present in all fresh meats (beef, pork, and poultry) at fairly constant levels, unlike the other biogenic amines that occur in

varying amounts. Other predominant biogenic amines in fresh meats are putrescine and cadaverine, together with relatively lower levels of histamine, tryptamine, and tyramine (Paulsen and Bauer 2007, Galgano et al. 2009). For beef, tyramine or a combination of the three most prevalent biogenic amines, tyramine, putrescine, and cadaverine, have been recommended for use as index of quality or spoilage (Vinci and Antonelli 2002).

Fresh poultry meat can also have significant amounts of biogenic amines and the accumulation of compounds such as spermidine, putrescine, cadaverine, histamine, and tyramine tend to increase during storage. In poultry, putrescine and cadaverine tend to be the predominant biogenic amines and may attain total levels of 50–100 mg/kg when stored over extended periods. Biogenic amines also accumulate more rapidly in raw poultry meat because of the higher susceptibility of white muscle fibers to proteolysis versus the darker muscle fibers of red meats, beef, or pork (Perez et al. 1998, Balamatsia et al. 2006, Patsias et al. 2006).

Enterobacteriaceae species are believed to be primarily responsible for putrescine, cadaverine, and histamine formation in poultry meat. Other microorganisms that have been identified as major biogenic amine producers include *Brochothrix thermosphacta, Carnobacterium divergens, Carnobacterium piscicola, Citrobacter freundii, Enterobacter agglomerans, Escherichia coli, Escherichia vulnaris, Hafnia alvei, L. curvatus, Morganella morganii, Proteus alcalifaciens,* and *Serratia liquifaciens* (Masson et al. 1996, Pircher et al. 2007).

Biogenic amine formation and/or accumulation in non-fermented meats are influenced by essentially the same factors as for fermented meats. For example, the type of meat is important, as it determines the availability of the substrate or precursor molecules. Relatively larger quantities of cadaverine are produced in both red and white meat due to the high levels of free lysine in both muscle types; however, red meats tend to have higher tyramine contents from their higher free tyrosine contents.

In fresh meats, temperature, salt content, and pH all play an important role in biogenic amine production. However, this attribute varies from species to species. For example, low pHs enhance the production of histamine, tyramine, and tryptamine in poultry meats by lactic acid than at a higher pH, while *Enterobacteriaceae* produced less cadaverine at low pHs. High salt concentrations also has a greater inhibitory effect on the formation of biogenic amines, and this is due to inhibition of microbial growth by the reduced A_w from the high salt content; higher temperatures promote more biogenic amines formation in beef, pork, and poultry samples than frozen temperatures. Thus, a higher salt content or lower storage temperature (or both) is recommended for curtailing biogenic amine formation and extending the shelf life of meat products (Chander et al. 1989, Karpas et al. 2002).

SIGNIFICANCE TO THE FOOD INDUSTRY

Biogenic amines are of particular interest to the food industry due to their toxicity, and their use as indicators of food quality or spoilage (Ruiz-Capillas and Moral 2004). For example,

histamine poisoning occurs following ingestion of foods that have large quantities of histamine (Stratton et al. 1991). Scombroid fish if not handled properly can accumulate high quantities of histamine, and such products can pose a health hazard when consumed. Other fermented foods, such as cheese, wine, dry sausage, sauerkraut, miso, and soy sauce have also been linked with biogenic amines poisoning. Histamine and tyramine toxicities have been extensively investigated, and biogenic amines such as β-phenylethylamine and tyramine have been linked to hypertensive crises (Shalaby 1996) and migraines. Other biogenic amines such as the HCAs have also been implicated in the formation of mutagenic or carcinogenic nitrosamines (Stratton et al. 1991), and the potential health risks of these compounds are areas of active research to better understand the extent of the health hazards posed by these compounds in food products.

HEALTH EFFECTS

Biogenic amines participate in various functions connected with cell growth and metabolism in humans. For example, spermine and spermidine are involved in free radicals scavenging, cell membrane channels modulation, and in DNA synthesis. However, the compounds must be present in minute quantities to carry out useful functions, because they can be toxic in high quantities. Other biogenic amines, such as histamine and tyramine, occur naturally in small quantities and participate in allergic and inflammatory responses (Khan et al. 1992, Ha et al. 1998, Schneider et al. 2002). The metabolism of histamine entails absorption by active or passive transport through the lumen of the GIT. During this passage, most of the histamine is broken down by the enzymes diamine oxidase (DAO) and histamine-N-methyltransferase (HNMT) into useful intermediates like imidazoleacetic acid and N-methyl histamine. These molecules together with the residual histamine are transported in the blood to the liver where they are degraded further. In the body, histamine binds to receptors to initiate various responses, including smooth muscle contraction, vasodilation, alteration of blood pressure, and enhancing vascular permeability. Nevertheless, high levels of histamine are potentially toxic and this intoxication manifests itself within 2 hours after ingestion and may last up to 16 hours. The symptoms include allergic-type reactions and gastrointestinal problems in the form of nausea, cramps, vomiting, and diarrhea (Izquierdo-Pulido et al. 1999, Attaran and Probst 2002, Maintz and Novak 2007). Histamine intoxication can also manifest as neurological and cutaneous disorders in the form of dizziness, flushing, headache, rash, and itchy eyes. These symptoms are attributed to the release of nitric oxide from vascular endothelial cells to bring about vasodilation (Becker et al. 2001, Predy et al. 2003, Borade et al. 2007). In rare cases, histamine poisoning could cause severe hypotension, atrial arrhythmias, and loss of consciousness (McInerney et al. 1996).

Various factors may influence histamine toxicity. These include the use of drugs that inhibit mono- and DAO enzymes, thereby preventing detoxification of histamine by deamination, gastrointestinal diseases, alcohol consumption, and bacteria endotoxins. Other biogenic amines like putrescine and cadaverine can also compete for the same catabolic enzymes as histamine, thus inhibiting the effectiveness of histamine detoxification and making the toxic compounds accumulate highly in the plasma.

Although histamine intoxication is the type most commonly associated with biogenic amines, tyramine also has high toxicity. Ingestion of large quantities of tyramine-containing cheeses, alcohol, chocolate, and other dairy products can elicit tyramine intoxication, which manifests as headaches and elevated blood pressure (Millichap and Yee 2003, Panconesi 2008). Tyramine is catabolized rapidly in the small intestine by MAOs, and monitoring tyramine ingestion is crucial for individuals on MAO-inhibiting drugs as their ingestion could bring on hypertensive crisis (Schmidt and Ferger 2004, Vlieg-Boerstra et al. 2005). Tyramine poisoning can also cause nausea, vomiting, and even death from intracranial hemorrhage. There are also emerging concerns with nitrosamines because they can form carcinogenic nitrosamines with cadaverine and putrescine by reacting with nitrites (used to cure meats) or by serving as precursor molecules (Bover-Cid et al. 1999).

Certain drugs, for example, ephedrine and related compounds (amphetamines, phentermine, mazindol, and fenfluramine) can block the uptake of the biogenic amines NE and serotonin. Thus, they are able to suppress appetite and food intake, and there is interest in the development of thermogenic drugs that could act on appropriate biogenic amines to control obesity safely without increasing heart rate and blood pressure.

QUALITY INDICATORS

Biogenic amines are of interest and use to food scientists/food technologists due to their use as food quality indicators. Aqueous solutions of putrescine and cadaverine impart discernible and objectionable odors at levels of 22 ppm and 190 ppm, respectively. The relative contribution of flavor from biogenic amines to the overall food quality is not well established; rather, the main focus has been on their possible use as chemical indicators of food quality. The relationship between the amounts of particular biogenic amines in a food product and the extent of food spoilage has been used to estimate a parameter known as the chemical quality index (CQI) or the biogenic amines index (BAI) for fish, and this takes into account the concentrations of putrescine, cadaverine, histamine, spermine, and spermidine in the fish sample (Mietz and Karmas 1977). On the basis of this, the CQI is calculated as

$$\text{Chemical Quality Index [CQI]} = \frac{\text{Histamine} + \text{Putrescine} + \text{Cadaverine}}{1 + \text{Spermine} + \text{Spermidine}}$$

and a CQI value below 1 denotes a good quality product, a value between 1 and 10 is considered mediocre, while a value ≥ 10 connotes spoilage. The CQI or BAI concept was extended further as the beer BAI by taking into consideration the concentrations of other biogenic amines, tyramine, β-phenylethylamine, and

agmatine that occur in products like beer (Loret et al. 2005). The beer BAI is calculated as

$$\text{Beer BAI} = \frac{\substack{\text{Cadaverine} + \text{Histamine} + \text{Tyramine} +\\ \text{Putrescine} + \text{Phenylethylamine} + \text{Trytamine}}}{1 + \text{Agmatine}}$$

Hitherto, a beer BAI value below 1 indicates a good quality product, a value between 1 and 10 is considered as mediocre quality, while a value $\geq$10 connotes spoilage. For meats, the total content of putrescine, cadaverine, histamine, and tyramine may be used to determine freshness, with levels $\leq$5.0 μg/g meat indicating high quality products (Hernandez-Jover et al. 1997).

ANALYSIS METHODS

There are several analytical methods available for the detection, isolation, and quantification of biogenic amine levels in food products. These include chromatographic, fluorometric, and enzyme-linked immunosorbent assay (ELISA) methods.

EXTRACTION AND CHROMATOGRAPHY

Various chromatographic methods have been used to analyze biogenic amines. These methods all entail an initial extraction step to recover the amines from the food product using organic solvents, together with perchloric and trichloroacetic acids. The extract thus obtained may then be subjected to chromatographic separation methods such as ion-exchange column chromatography, paper chromatography, thin layer chromatography (TLC), gas liquid chromatography, and high-pressure liquid chromatography (HPLC; Moret and Conte 1996, Cinquina et al. 2004, Paleologos and Kontominas 2004). TLC is considered as the simplest of the chromatographic methods for the separation and quantification of biogenic amines (Shalaby 1996). It is effective, accurate, fairly rapid, relatively inexpensive, and can be applied to large sample sizes. HPLC methods are commonly used method for biogenic amine analysis because they are highly sensitive and reproducible, although they require relatively more sophisticated and expensive technology, and are more time-consuming and tedious to carry out compared with TLC (Shakila et al. 2001, Lange et al. 2002).

FLUOROMETRIC METHODS

Biogenic amines may also be determined by fluorometric methods. These methods also involve extraction, purification, and separation of the compounds as in the chromatographic procedures. However, in order to quantify particular biogenic amines, the eluant is mixed with a molecule to form a fluorescent product, and the degree to which it fluoresces at particular wavelengths is determined and used as a measure of the amount of the biogenic amine in a food product by comparing with known standards (Du et al. 2002).

BIOSENSORS

This technology is based on the recognition of biogenic amines by specific ligands such as enzymes, antibodies, receptors, or microorganisms. The binding of the amines to these ligands is "sensed" by electrochemical, mass, optical, or thermal sensors, and the degree of response is measured and correlated with the amount of the substrate (amines) present in the raw material or sample (Tombelli and Mascini 1998, Sarkadi 2009). Commonly used biosensors for biogenic amines include putrescine oxidase and DAOs (Carelli et al. 2007). These enzymes utilize O_2 to react with the amines and produce H_2O_2. The change in concentration (of O_2 or H_2O_2) is typically measured as changes in electric signal by electrodes (Prodromidis and Karayannis 2002).

ENZYME-LINKED IMMUNOSORBENT ASSAY

Biogenic amines in foods may also be measured by the ELISA. This method is based on the detection of N-amino derivatives of histamine using antibodies. The N-amino derivatives are synthesized from histamine before analysis using compounds such as p-benzoquinone or propionic acid esters. There are presently commercial ELISA test methods that are available for the analysis of histamine levels in wine, cheese, and fish (Serrar et al. 1995, Aygun et al. 1999, Rupasinghe and Clegg 2007). The ELISA method used to analyze wine sometimes yields slightly higher results than the HPLC method; however, the ELISA method has the advantage of being more rapid and less tedious to perform than the HPLC methods.

EFFECTS OF FOOD PROCESSING AND STORAGE

Food processing is an essential mechanism for controlling the biogenic amine levels in foods. Because of their high thermal stability, once amines are formed, their concentrations will not be significantly decreased during cooking and heating processes. Processing techniques such as evisceration, postharvest handling, freezing, salting, and smoking can greatly affect the biogenic amine content and quality of the final product.

EVISCERATION

Evisceration can help control fish quality. For example, Atlantic croaker and trout eviscerated directly after capture had a longer shelf life than their iced un-eviscerated counterparts, and the cadaverine and histamine concentrations were significantly less in the eviscerated samples versus those of un-gutted fish samples (Paleologos et al. 2004). This observation is due to a decrease in the load of microorganisms associated with the eviscerated fish compared with the un-eviscerated ones.

TEMPERATURE CONTROL

Biogenic amine levels in food products are also greatly influenced by storage temperature. Postharvest handling techniques like immediate icing are important in controlling biogenic amine

levels in fish because at the reduced temperatures, both enzymatic and microbial activities are considerably reduced, so the rates of formation of the biogenic amines and their accumulation in the products are correspondingly reduced.

SALTING

Salting can effectively inhibit biogenic amine formation particularly at high levels. In general, a higher salt content results in a reduced biogenic amine formation. This is because the high salt lowers the A_w of the milieu, and this can inhibit both the microbial and enzymatic activities that are required for the biogenic amine formation.

SMOKING

Smoking is a traditional method used to preserve fish. The fish is smoked, then frozen, and transported. Histamine content is found to increase during the smoking process and continues to accumulate during subsequent freezing (Zotos et al. 1995). Even though smoking may induce histamine production and nitrosamines formation, the high temperature applied in smoking can also curtail the growth and proliferation of harmful and/or spoilage microorganisms (Martuscelli et al. 2009).

REGULATIONS

Since high level of biogenic amines, for example, histamine and tyramine, are associated with food poisoning, their intake has to be limited. Even though not all amines are equally toxic, and toxicological levels are hard to ascertain due to synergetic effects between amines, permissible limits have still been proposed. Thus, fermented products that are prepared using good manufacturing practices may be expected to contain histamine, tyramine, and β-phenylethylamine concentrations of 50–100 , 100–800, and 30 mg/kg, respectively, and still considered safe and acceptable for human consumption (Nout 1994). Levels of histamine, cadaverine, putrescine, tyramine, and β-phenylethylamine in sauerkraut must not exceed 10, 25, 50, 20, and 5 mg/kg, respectively, and the total amount of biogenic amines in fish, cheese, and sauerkraut must be less than 300 mg/kg (Shalaby 1996). Furthermore, biogenic amine intake greater than 40 mg in a meal is potentially toxic.

As biogenic amines are not extremely toxic or associated with many fatal incidences, there are few general regulations controlling their concentration. Histamine, however, is a common concern and different countries have set up their own standards for these compounds in foods. For example, a level of 10 mg histamine for every liter of wine is considered as acceptable in Switzerland. In the United States, 20 mg histamine per 100 g canned fish is considered unsafe for human consumption, and 50 mg histamine per 100 g canned fish is considered as a health hazard by the Food and Drugs Administration (FDA 2001); the European Economic Community has set the acceptable level of histamine content in fish as 10–20 mg/100 g (Shalaby 1996); the Canadian Food Inspection Agency, has set the action level

of histamine as 20 mg/100 g in fermented products and 10 mg/100 g in scombroid fish products (CFIA 2005, Moret et al. 2005).

CONCLUSION

Biogenic amines are important food components found in many fermented and non-fermented food production. They are present as by-products of microbial activity in foods. The microorganisms are either present naturally, added for fermentation purposes, or are introduced through contamination. It is desirable to minimize the formation of biogenic amines due to their adverse effects on human health and their contribution to food spoilage and food losses. In particular, the levels of tyramine and histamine need to be below a certain threshold level in order to prevent toxic responses.

The study of biogenic amines is an ongoing field of research, with several foci. Analytical methods are constantly being developed and/or improved in order to quantify their presence more rapidly and accurately. Further studies are needed to generate the basic knowledge on the effects of ingestion, toxic limits, and interactions with other biological molecules, to facilitate the rationalization and formulation of more useful recommendations and regulations regarding their safe levels in food products.

Emerging Bacterial Food-Borne Pathogens and Methods of Detection

Catherine M. Logue and Lisa K. Nolan

Abstract: Bacterial food-borne pathogens cause significant human illness and misery worldwide. In this review, we focus on an examination of the bacterial pathogens associated with food-borne illness that are common, those that are emerging and those that are reemerging. This overview will provide the reader with an understanding of the importance of selected pathogens, the type of disease they cause and why they should still be considered as emerging pathogens. In this review, we also focus on some of the newer generation pathogens such as shiga toxin-producing *Escherichia coli*, *Arcobacter*, *Mycobacterium*, *Cronobacter*, and antimicrobial-resistant pathogens. The second portion of this review provides the reader with an overview of methods for the detection of pathogens from culture based to automated methods as well as immunologic and nucleic acid-based techniques. Finally, this chapter includes some overview of the next-generation technology for the detection and characterization of pathogens including microarray, biosensor, mass sensitive biosensors, and nanotechnology. We recognize that the world of food-borne pathogens is ever changing and as the pathogen poses greater challenges to the host so too does our ability to detect and identify it in shorter timeframes.

INTRODUCTION

The costs of food-borne illnesses in terms of human health and economic loss remain relatively unknown, but are likely to be substantial. However, data, as it pertains to the industrialized countries, do exist but are typically limited to a select few microorganisms; globally, the burden of food-borne illness remains poorly understood and presents a significant challenge to society in how to monitor and assess disease trends.

The World Health Organization seeks to respond to this data gap by estimating the global burden of food-borne illness. In the United States, estimates of food-borne illness have been reported as 48 million cases, 128,000 hospitalizations, and 3000 deaths annually (CDC 2011) placing an economic burden of US$152 billion on the nation, with an average cost of US$1850 per

illness (Schraff 2010). The Centers for Disease Control (CDC) annual food-borne disease report posted through the FoodNet data site reports incidences of illness based on data from ten sentinel sites across the United States. The data cover approximately 46 million people representing approximately 15% of the population. Current data suggest that the incidence of infections caused by *Campylobacter*, *Salmonella*, *Listeria*, and shiga toxin-producing *Escherichia coli* (STEC), *Yersinia*, and *Shigella* (CDC 2010) is declining.

While focusing on food-borne pathogens in this review it is important to define what this review means by an "emerging food-borne pathogen." Mor-Mur and Yuste (2010) suggest that there are pathogens not previously known (new pathogens), others that have arisen as food-borne (emerging pathogens), and others that have become more potent with other products (evolving pathogens). Emerging pathogens are therefore present strains that are adapting to stresses in new environments. Emerging pathogens that have newly arisen have been recognized as a pathogen for many years and are now associated with food-borne transmission (Meng and Doyle 1997, 1998, Sofos 2008). While a considerable number of pathogens are present and capable of causing disease in foods, there are over 200 recognized natural chemical and physical agents (Acheson 1999). Perhaps the most important and emergent are *Campylobacter jejuni*, *Salmonella typhimurium* DT104, *E coli* O157:H7, and other enterohemorrhagic *E. coli* (EHEC) and STEC, *Listeria monocytogenes*, *Arcobacter butzleri*, *Mycobacterium avium* sbsp *paratuberculosis*, *Aeromonas hydrophila*, and *Cronobacter sakazakii*. Other agents of emergence include prions, viruses, (noroviruses, hepatitis A, rotavirus), severe acute respiratory syndrome (SARS), and parasites such as *Ascaris*, *Cryptosporidium*, and *Trichinella*. Also of concern is the emergence of antibiotic-resistant strains in pathogens such as *Salmonella*, *Campylobacter*, *Shigella*, *Vibrio*, *Staphylococcus aureus*, *E. coli*, and *Enterococci*.

There are a number of factors that contribute or have had an influence on the changing trends in food-borne disease; Newell et al. (2010) provides an excellent overview of changes that have occurred and contribute to the changing trends in food-borne disease. Some of the highlights include: a rapid increase in the human population and a shift towards an aging population; an increasing global market for foods, transportation, travel, changes in eating habits, a greater population of immunocompromised, and changes in farming practices and so on.

Ray (2004a) cites other factors including some which overlap with Newell et al. (2010) that can be attributed to our recognition of how we can define an emerging food-borne pathogen. *There is an overall better knowledge of food-borne pathogens*: previously, outbreaks linked to foods were screened for a range of standard pathogens but over the years we have expanded the repertoire to include new pathogens. Perhaps our abilities to test for new pathogens are based on our understanding of them. Technologies incorporating molecular analysis and the use of genomics have expanded our capabilities of what to search for. So too does the technology available to rapidly screen and identify greatly expand our knowledge.

Improvements in regulations and the actions of regulatory authorities have enhanced our capabilities to rapidly identify and monitor for emerging threats. Regulatory authorities at the state and national levels are able to collate data regarding specific outbreaks and the modes of transmission or vehicles implicated in food-borne outbreaks. On the basis of this type of criteria it is possible to make recommendations regarding criteria for what is acceptable and what is not, as well as methods to detect pathogens of concern. These agencies have also developed or guide the development of appropriate sanitation procedures to reduce the risk of human disease or educate consumers in safe handling practices. In the United States, agencies such as United States Department of Agriculture Food Safety and Inspection service (USDA FSIS), and the Food and Drugs Administration (FDA) direct some of these activities, while in Europe, the European Food Safety Authority (EFSA) has a similar role.

Changes in the lifestyle habits of consumers have changed significantly in the last 50 years. These have included traveling, (domestic and international), changes in consumer eating habits, (close to half of every dollar earned is spent eating out), the types of food consumed has changed, and there are increases in seafood consumption, exotic foods, cheeses, and minimally processed or more fresh or natural foods as well as greater access to a larger variety of fresh and raw foods that are imported.

New processing technologies have led to faster and more efficient ways to produce foodstuffs for larger retail markets and consequently there is considerably more product distributed over a wide area—examples of the effects of this have been seen in the outbreak of listeriosis associated with the consumption of contaminated hotdogs distributed nationally (CDC 1998, Donnelly 2001).

Some additional factors that may contribute to the emergence of food-borne pathogens include the recognition of illness associated with multiple strains of *E. coli* termed STEC (Eblen 2007), or strains that appear to be emergent as a result of transfer of resistance and other genetic virulence properties (Fricke et al. 2009), additional factors that warrant inclusion here are also related to the transfer of antimicrobial resistance and the selection of drug-resistant strains, which can become dominant in a food system (Endtz et al. 1991, Aarestrup and Engberg 2001, Engberg et al. 2001, Nielsen et al. 2006, Logue et al. 2010) and have potential links to disease that is difficult to treat. Also of interest are the capabilities of certain pathogens to grow at refrigeration temperatures (*Listeria*, *Yersinia*, *Aeromonas*) and the ability to survive in low-pH (acid) foods (*E. coli* O157:H7, *Salmonella*, *Listeria*).

In this chapter, we address emerging food-borne pathogens of human disease and their potential impacts on human health and methods for their detection. In general, trends in addressing disease have shown a reduction (downward trends). The latest data from the CDC shows prevalence in sentinel states has been decreasing (CDC 2010).

EMERGING FOOD-BORNE PATHOGENS

Salmonella

Nontyphoidal *Salmonella* is a major cause of food-borne disease in industrialized countries. In the United States alone, it

is estimated that nontyphoidal *Salmonella* was responsible for 7039 illnesses per 100,000 people in 2008 (CDC 2010). The organism colonizes a range of hosts of food animals including poultry, cattle, and pigs and rarer animals such as bison (Li et al. 2004, Li et al. 2006, Mor-Muir and Yuste 2010). *Salmonella* has also been found in a range of other habitats including soil, water, sewage, and so on.

Salmonella outbreaks are relatively common and have been associated with a range of foods and meats including poultry, beef, pork, and so on. Of interest are outbreaks of illness associated with more unusual foodstuffs such as chocolate, (Werber et al. 2005), shell eggs (Gantois et al. 2009), produce (Franz and van Bruggen 2008), tomatoes (CDC 2005a), and peanut butter (CDC 2009). Currently, there are over 2000 serotypes of *Salmonella* recognized (Ray 2004b) and annual trends from the CDC report common serotypes implicated in food-borne illness. The top two serotypes implicated include *S. typhimurium* and *Salmonella enteritidis* (CDC 2010) http://www.cdc.gov/ncidod/dbmd/phlisdata/*Salmonella*.htm; some novel strains also emerge on a regular basis.

Symptoms of human salmonellosis are usually observed as uncomplicated enteritis and enteric (typhoid) fever, which can result in a more complicated disease involving diarrhea, fever, abdominal pain, and headache. Systemic infection may also occur resulting in a chronic reactive arthritis (Smith 1994). *Salmonella* invades the mucosa of the small intestine and can proliferate in the epithelium, and produce a toxin, which causes inflammation and fluid accumulation in the intestine. The infectious dose required to cause illness is relatively high, about 10^5–10^6 organisms. Most individuals develop symptoms within 24–36 hours but the incubation time may be longer if the dose ingested is lower. Symptoms usually last 2–3 days but patients may remain carriers for periods of months after recovery.

Of greatest concern are *S. typhimurium* DT104 strains exhibiting multiple antimicrobial resistance to ampicillin, chloramphenicol, streptomycin, sulfonamides, and tetracycline (ACSSuT), most of the resistance appears to be chromosomally encoded (Threlfall 2000). These strain types have been recognized worldwide and have also caused infection in humans through consumption of contaminated foods including chicken, beef, pork sausages, and meat paste and also through occupational contact with cattle (Wall et al. 1995, Mor-Mur and Yuste 2010). In recent years, the incidence of *S. typhimurium* DT104 appears to be declining, while resistance to other antimicrobials including extended spectrum β-lactamases appears to be increasing (Newell et al. 2010) and have been detected in both humans and animals (Hasman et al. 2005).

Campylobacter

Next to *Salmonella*, *Campylobacter* is the most common cause of human food-borne disease annually in developed countries. In the European Union, *Campylobacter* is the most common cause of acute food poisoning; over 20,000 cases were reported in 2007 compared to 150,000 cases of salmonelosis (Westrell et al. 2009). In the United States, *Campylobacter* is the second most common cause of disease (gastroenteritis) responsible for approximately 845,000 illnesses annually and almost 100 deaths (CDC 2011). *Campylobacter* gastroenteritis is typically associated with *C. jejuni* and *Campylobacter coli*.

Campylobacter is found in a range of animal hosts including cattle, lamb, pigs with poultry being implicated as a primary source (Niesen et al. 2006, Nachamkin 2007, Mor-Mur and Yuste 2010). Additional sources of *Campylobacter* include water, sewage, raw milk, raw meats, and vegetables (Meng and Doyle 1998, Chan et al. 2001, Inglis et al. 2004, Nachamkin 2007). Prevalence levels of *Campylobacter* in food animals vary significantly, while *Campylobacter* levels on pork products are relatively low and may be related to postslaughter chill and drying effects, which significantly reduce the populations (Snijers and Collins 2004). Raw and undercooked poultry appear to be primary sources of *Campylobacter* associated with food-borne illness (Olson et al. 2008, Mor-Mur and Yuste 2010, Newell et al. 2010).

Campylobacter is a gram-negative organism and is a microaerobe with a requirement for low oxygen (microaerophilic) and a temperature range of 35–42°C for growth. The organism is generally a poor competitor, is sensitive to low pH, temperatures less than 30°C, pasteurization temperatures, and drying (Doyle and Jones 1992). It does, however, appear to survive under refrigeration temperatures and freezing may cause cell reduction but low levels of pathogen have been recovered (Blaser et al. 1980, Jacobs-Reitsma 2000). The organism does not survive well in foods and is easily destroyed by adequate cooking temperatures (Meng and Doyle 1998, Nachamkin 2007). *Campylobacter* is not capable of growth outside the host, but studies have demonstrated the survival of this pathogen on kitchen surfaces (Humphrey 2001).

The two major strains of *Campylobacter* implicated in the majority of human *Campylobacter* enteritis are *C. jejuni* and *C. coli*. Typical cases of human campylobacteriosis include diarrhea, abdominal cramps, profuse diarrhea, nausea, and vomiting; other symptoms include fever, headache, and chills, in some cases bloody diarrhea can occur, recurrence of symptoms (relapse) is often reported. Symptoms of illness are usually observed within 2-5 days of ingestion of contaminated food and can persist for up to 2 weeks. The infectious dose required to cause illness is relatively low and is estimated at approximately 500 organisms (Robinson 1981, Black et al. 1988). Additional complications recognized include reactive arthritis, pancreatitis, meningitis, endocarditis, and Guillain–Barré syndrome a postinfection complication of campylobacteriosis that causes peripheral nervous system paralysis resulting in a flaccid paralysis of the limbs, which can be life threatening (Blaser and Engberg 2008, Jacobs et al. 2008).

Outbreaks of campylobacteriosis typically occur in the summer months with most being sporadic in nature (Olson et al. 2008). Most outbreaks have been linked with improperly prepared or consumption of cross-contaminated, poorly handled poultry (Alketruse et al. 1997, Friedman et al. 2000).

Of significant importance is the prevalence of antibiotic resistance to agents such as fluoroquinolones and macrolides, two of the primary agents used to treat human disease (Engberg et al. 2001, Lutgen et al. 2009). Studies have reported

fluoroquinolone resistance in human isolates and those of production animals (Endtz et al. 1991, Engberg et al. 2001), while resistance to other antimicrobials has also been recognized including macrolides, tetracycline, aminoglycosides, β-lactams, and so on (Olah et al. 2006, Zhang and Plummer 2008, Lunagtongkum et al. 2009, Logue et al. 2010).

Resistances observed have been linked to the use of antimicrobial agents in food production animals, which can result in the selection or creation of drug-resistant strains (Endtz et al. 1991, Engberg et al. 2001, Logue et al. 2010). In *Campylobacter*, antimicrobial resistance is associated with a range of mechanisms including efflux pumps and point mutations (Lin et al. 2002, Taylor and Tracz 2005, Olah et al. 2006, Zhang and Plummer 2008, Logue et al. 2010, Guo et al. 2010). For detailed reviews of antimicrobial resistance mechanisms in *Campylobacter*, see Taylor and Tracz (2005), Zhang and Plummer (2008), and Lunagtongkum et al. (2009).

Pathogenesis in *Campylobacter* is associated with the ability to invade host cells, motility, and the production of cytolethal distending toxins which causes diarrhea (Nachamkin 2007); the presence of the pVir plasmid also appears to have a role in pathogenesis (Larsen and Guerry 2005). While *Campylobacter* appears to have emerged as a pathogen of human concern, its recognition as an agent of significant importance in human disease and its standing as the primary or secondary most common food-borne pathogen warrants its continued study.

Escherichia coli Including STEC

While *E. coli* is a common contaminant of meats, of significance are strains implicated in human disease including EHEC and other STEC. EHEC have been recognized as a significant cause of hemorrhagic colitis and complications associated with infection including hemolytic uremic syndrome (HUS) and thrombocytic purpura TTP (Ray 2004d). The organism was first recognized in 1982 as the cause of two major outbreaks of hemorrhagic colitis (Meng et al. 2007). Since that time, other serotypes associated with hemorrhagic colitis have been recognized and the list continues to grow. More than 600 serotypes of STEC are recognized and about 130 different types of EHEC have been recovered from patients presenting with hemorrhagic colitis (Meng et al. 2007).

One of the most common agents of EHEC is *E. coli* O157:H7, which has caused devastating disease worldwide. O157 strains are typically associated with beef cattle, beef, and beef products; however, other sources of the organism are now recognized including domestic and wild animals as well as meats, milk, vegetables, and so on. (Ray 2004d, Meng et al. 2007, Mor-Mur and Yuste 2010). Sources typically implicated include beef, beef products, luncheon meats, salami, and more recently outbreaks have been linked to unusual foods such as spinach and apple juice (CDC 1997b, CDC 2002, CDC 2006, Mor-Mur and Yuste 2010).

Of importance with O157 is the low dose (<100 organisms) required to cause human illness, which has been reported worldwide (Meng and Doyle 1998, Ray 2004d, Meng et al. 2007). The pathogenesis of *E. coli* O157 and other STEC is related to its ability to adhere to the host cell membrane, colonize the large intestine, and produce cytotoxic factors and cytolethal toxins including Shiga toxins. Toxins produced can become absorbed into the bloodstream where they cause further damage of blood vessels of the intestine, kidneys, and brain.

Symptoms of infection usually occur within 3–9 days after consumption of contaminated foods and generally last 4 days. Colitis symptoms usually include sudden onset of abdominal cramps, watery diarrhea, which in some cases becomes bloody (about 35–75% of cases can become bloody), followed by vomiting. The presence of toxins in the bloodstream cause breakdown of red blood cells and can cause clotting in small blood vessels of the kidney, which can cause kidney damage and failure, thus resulting in HUS. *E. coli* O157 infections can be fatal in young children. In addition, *E. coli* O157:H7 can cause brain damage as a result of TTP where blood clots in the brain lead to seizures and coma or death.

The largest outbreaks of *E. coli* O157 have been associated with ground meats (e.g., CDC1997a, CDC 2002); other sources of the organism have included raw milk, apple cider, fermented meats such as salami and pepperoni, sprouts, spinach, salads (CDC 1995a, 1995b, CDC 1997b, 1997c, CDC 2005b, CDC 2006, CDC 2008).

E. coli O157:H7 does not grow well at temperatures more than 44.5°C but does appear to have increased acid tolerance. The pH range for growth is 4–4.5 (Meng et al. 2007). *E. coli* O157 strains also display resistance to antimicrobials including streptomycin, tetracycline, and sulfisoxazole, which appear to be the most common resistance profiles observed (Meng et al. 2007) and care should be take when prescribing antimicrobials for treatment of disease as it may exacerbate illness. The importance of *E. coli* O157:H7 as an emerging (and continuing to emerge) pathogen that warrants its continued status as a significant pathogen of human concern; the observation of novel foods that have been implicated in human illness is ever changing, warranting careful monitoring.

Listeria monocytogenes

L. monocytogenes is a gram-positive organism that is ubiquitous in nature and found in a range of environments. Of all the *Listeria* species, *L. monocytogenes* is of primary importance in human disease. The organism can be a significant health risk for the unborn, newborns, infants, the elderly, pregnant women, and immunocompromised individuals.

Listeria is a psychrotroph, capable of growth at refrigeration temperatures, which poses a significant health risk and has been linked to food-borne outbreaks (Lianou and Sofos 2007, Swaminathan and Gerner-Smidt 2007). Therefore, contamination of postprocessed foods may pose a significant health risk to susceptible individuals.

While the incidence of listeriosis in the United States is relatively low, the CDC estimates about 2500 cases occur per year with 500 deaths. *Listeria* is a significant public health concern because of the severity of disease in susceptible populations. Individuals exposed to *Listeria* usually through the consumption of contaminated foods may or may not present with symptoms

of infection. Incubation times of 2–70 days after eating contaminated foods have been reported (Bortolussi 2008). Often, the symptoms appear as a mild flu-like illness with slight fever, abdominal cramps, and diarrhea. In healthy individuals, the symptoms usually subside with no significant side effects; patients do, however, continue to shed the pathogen for considerable periods postinfection (Marth 1988). In susceptible individuals, the initial listeriosis infection results in enteric symptoms with nausea, vomiting, abdominal cramps, diarrhea, fever, and headache being common. However, as the pathogen leaves the gut resulting in a systemic infection the symptoms change. In pregnant women, infection of the fetus can occur *in utero* resulting in abortion or preterm delivery; alternatively, the infant may present with symptoms of infection early (<7 days) or late (>7 days) postdelivery. Infants diagnosed early (<7 days) are most likely infected transplacentally, while those presenting with listeriosis late (>7 days) do not appear linked to maternal infection but the sources of infection are poorly understood (Bortolussi 2008). Symptoms of infection in infants and the immunocompromised include bacteremia, meningitis, encephalitis, and endocarditis. Fatality rates in unborn and newborn infants may be as high as 50% and has an average case fatality rate of 20–30% in others (Swaminathan and Gerner-Smidt 2007).

The infective dose to cause illness is considered to be 100–1000 cells; however, individuals that are compromised may be susceptible to lower doses (Ray 2004c). Cooked and ready-to-eat meat and poultry have been implicated as sources of the pathogen, and the growth of the organism has been demonstrated in refrigerated ready-to-eat meats and raw foods that may pose as significant health risk for consumers (Lianou and Sofos 2007, Swaminathan and Gerner-Smidt 2007).

The pathogenesis of *Listeria* is associated with the invasive ability of the organism, its ability to evade the host defenses, the ability to produce a hemolysin called listeriolysin O, and cross the blood–brain barrier (Drevets and Bronze 2008). Despite our knowledge of *Listeria* and methods of its control, the pathogen is still a significant risk to populations within the community and education of consumers is essential to ensure the safety of certain foods such as ready-to-eat meats and vegetables.

Arcobacter

The genus *Arcobacter* was first introduced in 1991, when it was identified as a distinct member of the family Campylobacteraceae (Vandamme et al. 1991, Vandamme and De Ley 1991). There are currently six recognized members of the genus including *A. butzleri*, *Arcobacter cryaerophilus*, *Arcobacter skirrowii*, *Arcobacter cibarius*, *Arcobacter halophilus*, and *Arcobacter nitrofigilis* (McClung et al. 1983, Houf et al. 2005). Although the organism still remains relatively unknown, *Arcobacter* is recognized as an opportunistic pathogen and a commensal and an emerging pathogen of human concern (Ho et al. 2006, Snelling et al. 2006).

To date, studies have found *Arcobacter* is a contaminant of water and foods of animal origin. *Arcobacter* have been associated with abortion in bovine, porcine, and ovine (Vandamme et al. 1992a,b, On et al. 2002). On et al. (2002) suggests that

some strains of *Arcobacter* play a primary role in abortions and reproductive disorders, while other stains may be opportunistic pathogens. Regardless, *Arcobacter* has frequently been associated with production animals and it appears that animals can be healthy carriers (Hume et al. 2001). The organism has been recovered from the feces of healthy animals including poultry (Houf et al. 2005), cattle (Wesley et al. 2000, Kabeya et al. 2003), pigs (Hume et al. 2001, Kabeya et al. 2003, Van Driessche et al. 2004), lamb, and equines (Van Driessche et al. 2003). Poultry appear to be a significant source of the pathogen with contamination occurring on carcass surfaces. Gude et al. (2005) reported that *A. butzleri* was commonly found in poultry abattoirs with carcasses being contaminated during processing. Atabay and Corry (1997) suggest that although there is a high prevalence of *Arcobacter* on poultry, the organism does not appear to be common in the gut of poultry suggesting that contamination of carcasses may arise from other sources during processing.

Arcobacter is a gram-negative organism capable of growth under aerobic and anaerobic conditions; however, optimal growth appears to occur under microaerobic conditions (3–10% O_2). The organism is considered a potential zoonotic agent due to its association with animals and the detection of *Arcobacter* in foods of animal origin including chicken, pork, lamb, and beef (Kabeya et al. 2004, Rivas et al. 2004, Morita et al. 2004, Lehner et al. 2005). *Arcobacter* have also been associated with water including a water reservoir, river or surface water, ground water, and sewage (Diergaardt Jacob et al. 1993, Rice et al. 1999, Stampi et al. 1999, Moreno et al. 2003, Morita et al. 2004, Diergaardt et al. 2004).

Although the organism is relatively unknown, it has been recognized as a potential agent of enteric disease and extraintestinal invasive diseases such as septicemia and bacteremia (Ho et al. 2006). In animals, *Arcobacter* has been recognized as a cause of diarrhea and hemorrhagic colitis (Vandamme et al. 1992a, Vandamme 2000). While in humans, *Arcobacter* was reported as the fourth most common *Campylobacter*-like organism isolated from the stool of human patients in Belgium and France (Vandenberg et al. 2004, Prouzet-Mauleon et al. 2006).

As mentioned above, *Arcobacter* is capable of growth under aerobic and anaerobic atmospheres with optimum growth under microaerobic conditions. The organism has a growth range of 15–37°C with an optimum of 30°C. This strict growth range may explain the lack of detection of the organism in the gut of poultry where the temperature is about 42°C. *Arcobacter* does also possess distinct abilities for growth at 15°C, which differentiates it from *Campylobacter* spp. *Arcobacter* can grow at a pH range of 5 and 8.5 with an optimum of 6 and 8 at 30°C (Hilton et al. 2001). Storage at 4°C resulted in a 4 log reduction over 21 days and freezing at −21°C resulted in a 2 log loss after 24 hours but remained constant thereafter.

Evidence suggests that there is an association between *Arcobacter* and human disease with food playing a role; however, the factors associated with *Arcobacter* and human disease are not well understood and warrant further investigation of the epidemiology, pathogenesis of and nature of this organism.

Mycobacterium avium Subsp *paratuberculosis*

M. avium sub species *paratuberculosis* (MAP) is a relatively new emerging disease of human illness. The organism MAP is part of a complex group of related organisms (Motiwala et al. 2006). The organisms within the group have high-level identity at the genetic level but differ in host source, disease phenotypes, and pathogenicity. Members of the group identified as *M. avium* are associated with disease in both animals and humans. Of interest is the association between *M. avium* and immunocompromised patients (AIDS) and its links to Chron's disease (*Mycobacterium paratuberculosis*) (Harris and Lammerding 2001, Greenstein 2003, Ghadiali et al. 2004, Karakousis et al. 2004). *M. paratuberculosis* is recognized as the causative agent of Johne's disease in ruminants and is recognized by chronic gastroenteritis, which can be debilitating.

In humans, Chron's causes a similar type of disease to that observed in animals and may be linked with MAP (Harris and Lammerding 2001); the association between Chron's disease and MAP does, however, remain controversial. Chron's disease appears to occur in a range of age groups of the population with cases observed in adolescents and in patients older than 50 years.

Recognized sources of MAP include the feces of infected animals, the environment, milk, foods, and contaminated drinking water (Glover et al. 1994, Grant et al. 1998, Yoder et al. 1999, Argueta et al. 2000, Grant et al. 2000, Raizman et al. 2004, O'Reilly et al. 2004). Methods using polymerase chain reaction (PCR) are valuable for the detection of MAP because of the extended periods of incubation required to detect the pathogen and the state of the cells that may make the organism difficult to detect by standard culture methods.

MAP may also be linked to milk. Studies have demonstrated that the organism survives pasteurization and may be present in raw and pasteurized milk. Grant et al. (1998, 2000) reported on the detection of MAP in milk using immunomagnetic separation (IMS). More recent studies have found the prevalence of MAP to be 12% in raw milk and 9.8% of pasteurized using IMS PCR. However, no viable cells were found, only DNA was detected suggesting that the pasteurization process destroyed cell viability. In the same study, only one raw milk sample was positive for MAP (O'Reilly et al. 2004). Others have assessed the prevalence of MAP in a range of produce from retail stores and supermarkets finding that of 129 foods sampled, 25 were positive for *Mycobacteria* with half of all isolates recovered identified as *M. avium* (Argueta et al. 2000). Yoder et al. (1999) demonstrated the relatedness of strains recovered from human disease with those found in foods, supporting the role of foods as a source of *Mycobacteria* for human disease.

In human cases of Crohn's disease, a chronic condition resulting in significant intestinal disease; it is recognized in three forms including inflammatory, structuring, and stenosing and fistulizing (Andres and Friedman 1999, Kirsner 1999). The primary location of disease is the distal ileum and colon. Currently, there is no known cure for Crohn's, with up to 74% of patients requiring surgery (Andres and Friedman 1999). Links between Chron's and MAP varies significantly and the epidemiology of the disease is not well understood although the or-ganism has been recovered from the tissues of Crohn's patients (Sechi et al. 2004). Treatment of Crohn's uses combinations of anti-inflammatories, steroids, and antibiotics until the patient experiences relief. Some antimycobacterial drugs used include rifabutin-macrolide-clofazimine (Shafran et al. 2000). Although the data on MAP are limited, its potential as an emerging foodborne pathogen at this time cannot be discounted and warrants further epidemiological studies.

Aeromonas hydrophila

The genus *Aeromonas* is a member of the family Aeromonadaceae and consists of 24 different species (Janda and Abbott 2010); this number is, however, continuously expanding with over 3500 new species proposed (Janda and Abbott 2010). *Aeromonas* is a gram-negative facultative anaerobe that appears to be ubiquitous in water and foods. The role of *Aeromonas* in food-borne disease is not well understood but is suspected and there is evidence of the pathogen in reported outbreaks. *Aeromonas* is capable of growth at refrigeration temperatures with an optimum growth range of 28°C and in a pH range of 5.5–9.

Most aeromonads are considered opportunistic in aquatic and terrestrial animals but can also be a pathogen of man and has been recognized as so since 1984 (Tsai and Chen 1996). Epidemiological evidence suggests that aeromonads can cause gastroenteritis in humans (Deodhar et al. 1991, Kuhn et al. 1997, von Grawvenitz 2007) and other complications such as wound infections, septicemia, and endocarditis (Janda et al. 1994, Broqui and Raoult 2001). *Aeromonas* appears to act as both an infectious agent and an enterotoxigenic pathogen (Kingombe et al. 1999). Members of the species of interest in food-borne disease appear to be associated with strains identified as *A. hydrophila*, *Aeromonas sobria,* and *Aeromonas caviae* (Gavriel et al. 1998). The relationship between motile aeromonads and food-borne illnesses is tentative; a few reports have linked illness to foods consumed such as shrimp cocktail (Janda and Abbott 1999) and oysters (Abeyta et al. 1990).

In humans, food-related *Aeromonas* illness is associated with gastroenteritis, with most cases affecting children, the elderly, and the immunocompromised (Isonhood and Drake 2002); annually it is estimated that *Aeromonas* may be responsible for up to 13% of all cases of gastroenteritis in the United States (Kingombe et al. 1999). The infectious dose of *Aeromonas* to cause human illness is unknown as is the mechanism of virulence; however, gastroenteritis, wound infections, and septicemia appear to be recognized as consequences of infection (Janda and Abbott 2010).

Aeromonas has been isolated from a range of foods and environments including retail vegetables, seafood, meats, cheese, and milk (Okrend et al. 1987, Abeyata et al. 1990, Kirov et al. 1993a, 1993b, Pon et al. 1995, Saad et al. 1995, Tsai and Chen 1996, Kuhn et al. 1997, Gavriel et al. 1998, Yadav and Verma 1998).

As with other emerging pathogens, our recognition of *Aeromonas* as an emerging pathogen of significant human

concern warrants further attention into the epidemiology of this pathogen and its relationship with human food-borne illness.

Cronobacter sakazakii (*Enterobacter sakazakii*)

Originally discovered in the early 1960s, this organism has primarily been associated with neonatal meningitis of newborns (Chenu and Cox 2009). Since then, the organism has gained increased attention as a pathogen of infants and newborns and was named *E. sakazakii* in the 1980s; as a consequence of genetic diversity, a new genus for the species was proposed in 2008 and named *Cronobacter*. This emerging pathogen has gained considerable attention in the past 10 years or so with much still to be learned about its epidemiology and pathogenesis.

Studies to date have implicated powdered infant formula (dried milk powder or a modified version) as the vehicle of transmission of the organism in some cases of neonatal meningitis (Simmons et al. 1989, Van Acker et al. 2001, Himelright et al. 2002, Caubilla-Barron et al. 2007, Hunter et al. 2008).

Cronobacter is a gram-negative rod, motile by peritrichous flagella and a member of the family Enterobacteriaceae. The genus consists of six species (Iversen et al. 2008). The organism has a growth range of 6–45°C with an optimum temperature of 37–43°C; *Cronobacter* is capable of growth at refrigeration temperatures, which may be a significant health risk (Iversen et al. 2004).

Clinical manifestations of illness have previously been associated with neonates and present as life-threatening meningitis, necrotizing enterocolitis, bacteremia, and septicemia (Muytjens et al. 1983, Van Acker et al. 2001, Lai 2001, Himelright et al. 2002). Case fatality rates as high as 80% have been reported; the survivors often suffer severe neurological disorders (Lehner and Stephan 2004) and long-term complications. *Cronobacter* illness has also been recognized in adults primarily among adults with underlying disease, the immunocompromised, stroke patients, and the elderly (See et al. 2007, Healey et al. 2010).

The pathogenesis of *Cronobacter* is not well understood but studies suggest that enterotoxins and the outer membrane protein OmpA may play a role in virulence and the ability of the organism to cross the blood–brain barrier (Iversen and Forsythe 2004, Townsend et al. 2007, Singamsetty et al. 2008, Mittal et al. 2009, Mohan Nair et al. 2009).

Cronobacter appears to have an environmental association; it has been postulated that plant material may be a source of contamination (Healey et al. 2010); new reservoirs of *Cronobacter* are being reported on a regular basis. Although the association between the gut of animals and *Cronobacter* is questionable, the organism has been found in water, soils, and plant materials (Iversen and Forsythe 2003). *Cronobacter* has also been recovered from a range of foods including meats, poultry, rice and other grains, vegetables, herbs and spices, dry food ingredients, breads, ultra-high temperature processed milk, cheese, sausage, tofu, keifir, and sour tea (Iversen and Forsythe 2004, Kandhai et al. 2004, Gurtler et al. 2005, Mullane et al. 2007, Friedemann 2007). Baumgartner et al. (2009) identified *Cronobacter* in ready-to-eat foods with 61% of sprout or fresh herbs and 27% of dried herbs or spices being positive for the organism. O'Brien

et al. (2009) detected *Cronobacter* in follow-on infant formula but not in powdered milk products suggesting that the risk of illness is low but monitoring of raw ingredients is necessary to establish sources of contamination.

One of the primary sources of illness in neonates appears to be associated with powdered infant formula. As the powder is nonsterile, it may become contaminated during production or reconstitution (Simmons et al. 1989, Van Acker et al. 2001, Caubilla-Barron et al. 2007). Also of concern is the ability of *Cronobacter* to produce biofilms, which may enhance its abilities to resist the killing action of disinfectants (Kim et al. 2007a). Regardless of the narrow scope and sources of *Cronobacter*, its recognition as an emerging pathogen warrants attention in light of its epidemiology and pathogenesis being poorly understood.

Clostridium difficile

Clostridium difficile is a gram-positive anaerobic spore former that has gained increased attention as a pathogen of human concern (Weese 2010). Originally, this organism was recognized as a pathogen associated with diarrhea as a result of antimicrobial treatment of patients. Now, however, there is concern that this organism may also be an agent of zoonoses (Songer 2010). Indra et al. (2009) reported that *C. difficile* is primarily considered a nosocomial pathogen causing diarrhea and pseudomembranous colitis, yet others have found that *C. difficile* is found in food production animals suggesting a potential relationship between humans and animals (Songer 2004, Weese 2009a).

The pathogenesis of *C. difficile* is usually associated with overgrowth of the organism in the gut resulting in mild to life-threatening pseudomembranous colitis, toxic megacolon, and/or intestinal perforation (Borriello 1998); changes in the gut microflora also appear to be linked to the overgrowth of *C. difficile* (Bartlett and Perl 2005). Two toxins are also recognized as contributing to pathogenesis—tox A and tox B and a third toxin CDT is also a contributing factor (Rupnik et al. 2005). In human disease, there has been an increase in the incidence of *C. difficile* associated with ribotype 027, which has been recognized as an epidemic strain worldwide (Goorhuis et al. 2008).

Recently, concern for *C. difficile* has escalated due to studies demonstrating the prevalence of the organism in animals and foods of animal sources, suggesting that community acquired *C. difficile* may contribute to human outbreaks. Studies to date are, however, limited and have used varying approaches to detect the pathogen. Indra et al. (2009) assessed the prevalence of *C. difficile* in cattle, pigs, and broilers demonstrating that 4.5% of cattle, 3.3% of pigs, and 5% of broilers were positive for the organism. A similar assessment of retail meat samples (ground beef, pork, and chicken) failed to detect the pathogen. In contrast, Songer et al. (2009) reported the prevalence of *C. difficile* in ready-to-eat meats and raw meats ranging from 14% to 50%. Of significance in the study was the detection of ribotype 027, a strain type that is almost exclusively associated with human disease worldwide and has been identified as an epidemic strain (Goorhuis et al. 2008). This ribotype has also been identified as possessing resistance to the fluoroquinolone class of antimicrobials (Razavi et al. 2007). *C. difficile* has also been found in

other food types including vegetables (Al Saif and Brazier 1996), ready-to-eat salads (Bakri et al. 2009), vacuum-packaged beef (Bouttier et al. 2010), retail ground meats (Jobstl et al. 2009), red meats, ground products, pork and chicken products (Rodriguez-Placios et al. 2007, 2009, Norman et al. 2009, Von Abercron et al. 2009, Weese et al. 2009b, Weese et al. 2010), and in swine operations with the highest prevalence levels observed in young animals (Norman et al. 2009). Speculation as to the sources of *C. difficile* on meat have included animal hides, processing equipment, the environment and employees, and noting that the spores are probably able to survive processing, cleaning, and disinfection (Weese 2009a).

Rupnik (2007) strongly suggests that the current data provide preliminary evidence or support speculation that animal reservoirs and transmission via foods may be a source of community-associated infections. Regardless, there are currently considerable knowledge gaps in our understanding of *C. difficile* and its links to food-borne disease; to date, there is no direct evidence of illness and an identified source, which suggests that a greater understanding of the epidemiology of *C. difficile* is warranted.

Antimicrobial-Resistant Pathogens

Although mentioned in regards to some of the pathogens discussed above, the emergence of antimicrobial resistance in food-borne pathogens warrants further review in this chapter. Doyle and Erickson (2006) consider that antimicrobial resistance in pathogens is a concern and will continue to be an issue for the future. Over the last 50 years or more, the use of antimicrobials has been a mainstay for the treatment of infectious disease in humans and animals. However, over the same period, the use of antimicrobials has led to the emergence of antimicrobial resistance in pathogens. Newell et al. (2010) considers that any kind of antimicrobial can select for emergence of resistance and promote the dissemination of resistant bacteria and resistance genes. As a consequence, resistance can be selected in the agricultural sector and can contribute to the public health burden. Woteki and Kineman (2003) and Teale (2002) suggest that the overuse of antimicrobials in agriculture and healthcare have been identified as contributing factors to drug-resistant strains. Food, therefore, can be both a source of antimicrobial-resistant bacteria and resistance genes; therefore, foods harboring antimicrobial-resistant bacteria can be a significant threat to human illness. Studies have highlighted the presence of resistant *Salmonella*, *Campylobacter*, *E. coli*, and other such pathogens in the food chain potentially contributing to disease.

Indirectly, these antimicrobial-resistant organisms can also be an indirect source of bacterial resistance by transferring resistance genes to other organisms or commensals. Studies have highlighted the role of mobile genetic elements in the transfer of resistance (Barlow 2009). Kruse and Sorum (1994) highlighted the transfer of resistance using plasmids. Regardless of how resistance occurs, and its complexities, antimicrobial resistance appears to have emerged in food-borne pathogens, thus posing a new challenge in understanding its epidemiology and the means to control it.

Some of the important antimicrobial-resistant pathogens include: *Salmonella*, there are well-documented studies of food-borne illness associated with drug-resistant *Salmonella*. The pathogen has been associated with a variety of foods including meats, eggs, produce, and so on. Studies have highlighted the movement of drug-resistant strains from food to humans (Endtz et al. 1991, Engberg et al. 2001). Other studies have linked drug use at the farm with the emergence of drug-resistant strains (Logue et al. 2003, Lin et al. 2007, Logue et al. 2010, Newell et al. 2010), thus leading to potential transfer to humans via foods or direct contact with animals.

In *Salmonella*, some species appear to have the ability to resist multiple antimicrobial agents. Multidrug-resistant *S. typhimurium* DT104 is an example of a strain possessing resistance to five different antimicrobials (Threlfall 2000). Newly emerging resistance to extended spectrum β-lactam antimicrobials has also become an issue (Patterson 2006, Carattoli 2008).

In *Campylobacter*, a similar situation has also been observed with poultry being a primary source of the pathogen and the intensive nature of poultry rearing has led to the emergence of drug-resistant *Campylobacter*. In recent years, the emergence of fluoroquinolone-resistant *Campylobacter* has been observed and in some countries, the emergence of resistance has been linked to the use of fluoroquinolones in poultry production (Aarestrup and Engberg 2001, Humphrey et al. 2005) and a consequent increase in fluoroquinolone-resistant strains occurring in humans (Endtz et al. 1991, Engberg et al. 2001). In light of this evidence and the potential risks for food-borne disease, the use of fluoroquinolones for use in poultry production was banned in 2005. Regardless of the ban, however, it would appear that fluoroquinolone-resistant *Campylobacter* are still present in production birds and meat (Price et al. 2007, Han et al. 2009a). In addition, the emergence of macrolide-resistant *Campylobacter* is also of concern. Lin et al. (2007), Lunagtongkum et al. (2009), and Logue et al. (2010) highlighted the effect of dosing to select resistant strains, however, in the absence of selective pressure, levels of resistant strains appear to drop in favor of nonresistant strains, suggesting that the fitness cost associated with resistance maintenance may be too high to promote persistence (Han et al. 2009b, Hao et al. 2009, Logue et al. 2010).

In *E. coli,* the emergence of multidrug-resistant strains has also been evident. Commensal *E. coli* may also be a source of resistance to other *E. coli* and pathogens. Studies by our colleagues have highlighted resistance carried on plasmids that form islands of resistance (Johnson et al. 2004, Johnson et al. 2010) and appear to be co-selected with virulent strain types, suggesting that virulence and resistance are complementary (Johnson and Nolan 2009). Travers and Barza (2002) noted that drug-resistant strains appear to be more virulent than drug susceptible strains. In addition, transfer of resistance genes from *E. coli* to other pathogens has been demonstrated and has been shown in both the animal and human gut (Gast and Stephens 1986, Su et al. 2003, Poppe et al. 2005,Yan et al. 2005) and in foods (Kruse and Sorum 1994, Walsh et al. 2008).

In gram-positive organisms, methicillin-resistant *S. aureus* (MRSA) has emerged as a significant problem; once thought of as a nosocomial infection, community acquired MRSA have

been identified as a potential zoonoses following detection of the pathogen in a range of animal hosts. MRSA strain types have been isolated from pigs (De Boer et al. 2009) and a prevalence of MRSA in retail meats of 11.9% was also observed with highest prevalence in poultry meats.

Resistance of food-borne pathogens is currently monitored in the United States through the National Antimicrobial Resistance Monitoring System. There are two branches that follow and assess drug resistance in animal production and foods of animals and also the clinical side of disease. Trends in resistance are released annually and indicate emerging resistance types and changing profiles for *Salmonella*, *E. coli*, *Campylobacter*, and some gram-positive organisms (see http://www.cdc.gov/narms/ and http://www.fda.gov/AnimalVeterinary/SafetyHealth/Anti microbialResistance/NationalAntimicrobialResistanceMonitor ingSystem/default.htm). For further discussion on antimicrobial resistance in relation to food-borne pathogens the authors recommend the review by Cleveland McEntire and Montville (2007).

METHODS FOR THE DETECTION OF FOOD-BORNE PATHOGENS

In this section, we discuss some of the approaches used in detection of food-borne pathogens. The review discusses methods from the classical to the rapid to the next generation of technologies. While this section provides an overview of the most common methods used it is not comprehensive, as the field of rapid technologies is changing fast and newer technologies have taken advantage of nano sciences for their applications. This section covers detection methods; for detail on typing (see Logue and Nolan (2009)).

Culture-Dependent Methods

Detection of food-borne pathogens in a food sample usually involves increasing the population of the target organism present to levels that can be detected by conventional or other means. Typically, culture-dependent methods involve a series of enrichment phases designed to increase the population of the pathogen present, which can be followed by a second selective enrichment designed to selectively enrich the target pathogen, while inhibiting or suppressing the growth of contaminant flora that may also be present. The method for culture enrichment is relatively straightforward and for the primary enrichment usually involves volumes about 25 g of the suspect food in 225 mL of a nonselective enrichment broth (a 1:10 ratio of sample to enrichment broth is typically recommended). The sample is homogenized and then incubated at a temperature optimum for the target pathogen with an incubation time in the region of 18–24 hours. Following the primary enrichment, a secondary enrichment designed to select the pathogen and suppress contaminants is usually carried out. In this case, the selective enrichment phase, media, and ratios of sample to selective broth are significantly reduced and volumes of 0.1–0.5 mL (or at slightly higher ratios if needed) of the primary enrichment broth are transferred to 9.9–9.5 mL volumes of the secondary

broth. Secondary enrichment broths are usually incubated for a further 18–24 hours at the optimum temperature of the pathogen. Incubation temperature for the selective broth can be the same or different from the temperature used for the primary enrichment broth. Following secondary enrichment, the sample is typically struck to a selective or differential agar designed for specific isolation of the target pathogen. Incubation of selective agar plates to recover the target can take an additional 24–48 hours (or longer for some pathogens) to determine presence of a suspect pathogen. Further confirmation and identification of a suspect pathogen from selective plates to the genus or species level may take an additional 4–5 days to complete using conventional biochemical methods, morphological analysis, serological analysis, or other such tests. Some of the post isolation analysis can be considerably shortened with the application of automated or molecular testing. While the methods such as those described here are considered the standard for detection of a target pathogen, they are recognized by federal agencies as the gold standard for the detection of bacterial contamination. Some examples of agencies who provide standardized methods online for use in the detection of pathogens in foodstuffs include the FDA Bacteriological Analytical Manual http://www.fda.gov/Food/ScienceResearch/LaboratoryMethods/ BacteriologicalAnalyticalManualBAM/default.htm; the USDA FSIS Microbiology Laboratory Guidebook http://www.fsis. usda.gov/science/microbiological_Lab_Guidebook/; other guides of importance include the American Association of Analytical Chemists (AOAC) and the International Standards Organization (ISO); additional standards and protocols are recommended on a national level for individual countries and the reader is advised to refer to the protocols recommended on a national level. While the use of standard methods is of value in pathogen detection, they have considerable drawbacks in terms of time and labor required to obtain a result and cost issues associated with isolation and detection; some of these methods also suffer in their detection capabilities (sensitivity and specificity) and may fail to provide adequate detection of the target pathogen if the medium is too selective for a particular strain type or the state of the organism may not allow its detection prior to application of the protocol. Other problems also complicating pathogen detection include nonuniform distribution of the pathogen in a sample, which can mean that dependent on where the sample is collected it may not be representative of the whole sample. Also, a low level of pathogen may be present in the sample, which may complicate its detection in the presence of high levels of natural microflora. The heterogeneous nature of the food matrix can also interfere with the growth or detection of the target pathogen. Finally, injured cells as a result of processing may result in inability to detect target pathogens using selective media.

Culture methods for the detection of a pathogen are therefore subject to limitations such as the initial number of organisms in a sample: (1) if the number of organisms in a sample is very low and the sample is enriched, competition from other naturally occurring microflora present in the sample may outcompete the target organism, other issues associated with competition may not only be competition for space and nutrients but also

production of by-products of metabolism that have a negative effect on the target organism such as acids and other inhibitory substances; (2) the state of the organism in the sample (injury status); studies have demonstrated that injured cells may need additional time to recover prior to any standard enrichment as they may not be able to grow in the presence of a selective agent, and so on, therefore, there is a risk in missing detection of the target; (3) selectivity of the enrichment media used—authors have noted that not all standard protocols may be adequate for detection of the target organism, there is evidence to suggest that some selective enrichment media may not be appropriate for detection of all target populations and that some strain types may be inhibited or missed as a result of the enrichment process, thus there is a risk that the protocol may not truly be reflective of the population in a sample. Wu et al. (2001) demonstrated some of the challenges posed in the detection and enumeration of *E. coli* O157:H7 in alfalfa seeds, an unusual food product that has been linked to outbreaks of human illness (Mohle-Boetani et al. 2001). Regardless of the approach taken, readers of this article should consider carefully the type of food matrix that requires testing and how it in itself may pose unique challenges to detection of the target pathogen.

In recent years, methods to automate and significantly shorten the detection time required have been implemented for some protocols used in the detection of pathogens and these can significantly reduce labor and time of detection. They do, however, come at a cost in terms of technology or specialized systems for detection, which may not be appropriate for all laboratory or production facilities.

AUTOMATED METHODS TO DETECT PATHOGENS

Commercial companies have considerably expanded their offerings in automated and rapid methods for the detection and identification of food-borne pathogens, while in some instances the methods are proprietary, the basic principle of the methods are relatively similar—examples of some of the more common commercial detection systems currently available include the VIDAS® system (BioMérieux), which has application for the detection of pathogens such as *E. coli* O157:H7, *Campylobacter*, *Listeria*, *Salmonella*, and so on in food systems. The VIDAS system is based on an immunoassay type reaction that can detect the pathogen in an enrichment culture in as little time as 45 minutes. The protocol does, however, require enrichment prior to detection and this can entail time frames of 6–24 hours.

The BAX® system (DuPont and Qualcon) is another automated system for the detection of pathogens such as *Campylobacter*, *E. coli* O157:H7, *Salmonella*, *Listeria, S. aureus*, and so on in foodstuffs using a real-time PCR-based assay. The BAX system can detect the pathogen directly in a sample (if heavy contamination is suspected) or following an enrichment phase. The BAX system uses a PCR-based protocol to amplify genes specific to the species of interest and detect presence of the organism through fluorescence of the amplified product.

The system is also capable of assessing the number of cells in a sample—the minimum detection limit for the technology is about 10^4 colony forming units (CFU)/mL, and can detect target pathogens in as little as 90 minutes. This technology has recently received AOAC approval for application in the detection of a range of pathogens.

Another rapid technology for the detection of pathogens includes the simple and relatively low-cost alternative called lateral flow kits. Lateral flow kits (Dipstick, DuPont) work on the principle of an antigen antibody reaction and are designed to detect the presence of antigens in a sample. The system uses specific enrichment media to increase the population of the target pathogen and then a test strip is added to an aliquot of the enriched sample, the strip employs a combination of antibodies specific to the target pathogen and gold colloidal particles on the surface of the membrane. The liquid sample wicks up the test strip by capillary action and if the target pathogen is present it reacts with the antibodies present to result in a color change and a visible line in the strip. This method has been available from a number of vendors and has proven successful for rapid screening of samples for target pathogens. Of concern, however, is the specificity of the antibodies used in the strip that may not be able to detect all strain types present in a sample. Fakhr et al. (2006) found that the a lateral flow kit can fail to detect *Salmonella* in some poultry samples that were positive for *Salmonella* by other methods including real-time PCR and selective culture, suggesting that specificity of the antibodies used in the assay may not always detect the target.

AUTOMATED METHODS OF IDENTIFICATION

Although not strictly part of this review, it is important to discuss the differences between detection of a pathogen and its identification. While there are a range of technologies available for the detection of pathogens, there are also a significant number of technologies available for the rapid identification of pathogens once detected. These include a range of automated systems that are based on biochemical tests or metabolic profiles Vitek – (BioMérieux) and Microstation (Biolog), or cellular fatty acid analysis systems (gas chromatograph based, Sherlock Microbial Identification system). In addition, there are multiple smaller rapid identification kits that can successfully identify a pathogen in a period of a few minutes to a few hours, these include systems such as microID, Trek's GNID, API, and so on; the majority of these kits are visual and based on biochemical reactions leading to changes in color (or fluorescence if read automatically, TREK GNID). In addition, DNA-based methods can successfully identify a potential pathogen by amplification of single or multiple genes associated with a particular species.

IMMUNOLOGIC-BASED METHODS OF PATHOGEN DETECTION

Immunological-based methods for pathogen detection rely on the binding of a bacterial antigen to a monoclonal or

polyclonal antibody. A range of different immunoassays are available for detection of pathogens these include the enzyme linked immunosorbent assay (ELISA), immunochromatic assay, and immuofluorescent assay. The sandwich ELISA is a commonly used technique for the detection of pathogens and is based on the application of an immobilized antibody on a solid surface (usually, a microtiter plate) followed by exposure of the antibody to a sample containing the target cells. The antibodies bind or capture the target cells. Once captured, the sample is washed to remove unbound cells and then a second antibody conjugated to an enzyme is added followed by addition of an enzyme substrate. A positive result is usually observed through the colorimetric detection of the product of the reaction between the enzyme and the substrate (see Fig. 44.1).

IMMUNOPRECIPITATION (*DIPSTICK/LATERAL* FLOW)

The lateral flow kit is an immunochromatographic method for the detection of pathogens. The sample is usually applied to a well and the sample is wicked from the sample port to an area containing antibodies conjugated to a precipitable material such as colloidal gold. If the target pathogen is present in the sample the antigen antibody complex moves to a second region where binding to a second antibody occurs resulting in an antibody – antigen – antibody complex which usually results in a colored immunoprecipitate (see Fig. 44.2).

Immunomagnetic Separation

Another application of immunologic-based detection is the use of antibody coated beads for the detection of pathogens in enrichment samples using immunomagnetic separation (IMS). Specially designed beads are coated with antibody specific to the pathogen of interest. The magnetic beads themselves are paramagnetic meaning that they are only magnetic in the presence of a magnetic field. Usually, the beads are mixed with a sample of the enrichment broth containing the target pathogen. Following a period of incubation to allow the antibody to react with the antigen of the target organism the beads are exposed to a magnetic field which captures the beads at the side of the tube. The remaining liquid is removed containing unbound organism, food components and remaining enrichment broth. The beads containing the bound cells is usually washed and then suspended in a small volume of diluent, which can then be plated directly on selective media to detect the target organism or further processed into a PCR reaction to detect the target pathogen or examined by other means such as immunofluorescence, and so on.

While the use of immunologic-based assays significantly enhances detection of pathogens in foods, there are however, some drawbacks to the use of immunologic-based assays; the first is the risk of cross-reactivity, due to the ability of the antibodies used to cross-react with nontarget antigens, thus leading to false positive results. In addition, most antibody-based assays have a minimum detection limit of about 10^4 CFU/ml; therefore, levels of the target antigen below this threshold may not be easily detected leading to false negative results.

Figure 44.1. Direct enzyme-linked immunosorbent assay for the detection of pathogens. **1.** The plate is coated with capture antibody. **2.** The test sample is added and the antigen (or target organism) binds to the capture antibody. **3.** An enzyme linked capture antibody is added as a detecting antibody and binds to the antigen. **4.** A substrate is added. **5.** The substrate is converted by enzyme to a detectable form (usually, a color reaction).
Figure 44.2. Rapid detection of pathogens using a lateral flow kit.

Latex Agglutination Assays

Latex agglutination assays use antibody coated colored latex beads or colloidal gold particles that will clump in the presence of a specific antigen. The test is based on the insoluble bacterial cells clumping in the presence of the antibody. In general, for latex agglutination assays to be accurate they require a pure culture for the specific assay as the sensitivity of the antibodies can be relatively low, thus resulting in cross-reactions. The test is however relatively fast, easy to perform and visual interpretation relatively straightforward. Latex assays have been developed for the detection of a range of organisms including *E. coli* O157:H7 and other STEC members, *Salmonella* spp, *Campylobacter* spp., *Listeria*, *Shigella*, *S. aureus*, *Vibrio* and *Yersinia*. One of the drawbacks of the latex agglutination assays is the potential for the particles to cross-react with other members of the same genus because of structural similarities in the lipopolysaccharide layer (Feng 2007).

A modification of the latex agglutination assay is the reverse passive latex agglutination (RPLA), in this assay the antibody is used to detect a soluble component of the bacterium – the toxin. Usually, toxins are soluble and will form a diffuse lattice network or layer in the presence of the antibody indicating a positive test. RPLA is typically carried out in a microplate to detect toxins in a food extract or pure culture suspension (Feng 2007).

Gel Immunodiffusion

The gel immunodiffusion assay was developed for the rapid detection of *Salmonella* in a food system. The test is based on the use an L-shaped chamber containing motility agar and antibodies against *Salmonella* flagella on one side of the chamber and on the other side, selective enrichment media for enhancing the growth of *Salmonella*. A sample is added to the enrichment medium side and growth of the pathogen will occur, over time, the pathogen will migrate through the motility agar where it cross-reacts with the anti flagellar antibodies resulting in a visible layer of precipitation in the motility agar. The test is relatively specific and has AOAC approval for use in the detection of *Salmonella* species. The test, however, is limited to motile *Salmonella* species and will not detect nonmotile strains. The test is marketed as a *Salmonella* 1-2 kit by BioControl.

NUCLEIC ACID-BASED DETECTION

Pathogen detection using nucleic acid-based approaches are usually designed to target DNA, RNA, or both. In recent years, there has been a rapid increase in the use of such approaches for not only detection of a pathogen but also for identification and characterization.

HYBRIDIZATION TECHNIQUES

DNA/Colony Hybridization

Colony hybridization is a relatively low-cost method for pathogen detection where colonies of a suspect target are selected from a plate and transferred to a solid support (e.g., membrane). The cells of the sample are then lysed using an enzyme to release the DNA. The DNA is then denatured to allow linkage to the support membrane and then hybridized to a gene probe with complementary sequence to the target DNA. Usually, the gene probe is labeled with a fluorescent tag or other color marker which allows easier detection of the pathogen. In recent years, the use of the solid support for detection of target DNA has changed slightly and the application of hybridization can occur through the use of a dip stick approach where the DNA is hybridized to probes embedded on a solid surface. Hybridization can also be achieved in solution. One such system that is commercially available with success in the detection of pathogens such as *L. monocytogenes* and *Salmonella* is the Gene-Trak kit marketed by Neogen.

Polymerase Chain Reaction (PCR)

PCR has revolutionized molecular studies and our approaches in detection and characterization of food-borne pathogens. The basic principle of the technique is that a thermostable DNA polymerase is used to amplify a specific region of DNA to detectable levels from template DNA found in the target pathogen. In conventional PCR methodology, the amplicons generated are then separated out by gel electrophoresis, the DNA stained, and the size of the DNA bands determined by comparison to standard DNA and a control strain. The use of such amplification techniques has expanded considerably over recent years and is used not only in the detection of a target pathogen but also for identification of pathogens in foods and other substrates, detection of genes associated with pathogenesis, virulence or toxins, and detection of viruses or fungi (Auvray et al. 2007, Kim et al. 2007b, Baert et al. 2008, Niessen 2008).

Newer PCR techniques are emerging, making this technique ever more useful for rapid assessment of a food. For example, PCR reactions are commonly configured to amplify multiple gene targets simultaneously; therefore, the application of PCR-based approaches has the capability to detect multiple pathogens concurrently. To work well, multiplex PCR protocols should use primer sets which ensure that amplification products are at least 30-50 bp apart, thus allowing adequate resolution if the amplification is followed by gel electrophoresis. Multiplex PCR reactions have been used in a number of ways including the simultaneous detection of multiple target pathogens in a mixed sample or matrix, for example, the detection of pathogens such as *Salmonella*, *Shigella*, *Listeria, E. coli O157:H7*, and so on in artificially inoculated foods (Alarcon et al. 2004, Kim et al. 2005, Kim et al. 2007b, Yuan et al. 2009, Kawasaki et al. 2010) and detection of multiple virulence or resistance genes in *E. coli* and *Salmonella* (Skyberg et al. 2003, Skyberg et al. 2006, Li et al. 2006, Johnson et al. 2007, Nde and Logue 2008). Martinez et al. (2006) used multiplex PCR for the simultaneous detection of three genes associated with the production of cytolethal distending toxin (CDT) in *C. jejuni* and found the prevalence of the genes to be 98% in human and animal isolates recovered from a wide European geographic origin. In a similar study, Asakura et al. (2008) developed a multiplex for *cdt* genes in *C. jejuni* and *C. coli*, with a minimum detection limit of 10–100 CFU.

When PCR is used in the detection of target genes from food matrices or mixed culture, the quality of the DNA that serves as template for amplification is of concern. Cultures and food matrices can contain substances which inhibit PCR (Fakhr et al. 2006); these include components such as carbohydrates, fats, polysaccharides and proteins; commercial PCR clean-up kits are available for reducing these effects. The efficiency of, or utility of PCR may be enhanced using different enzymes and labeling agents; specialty *Taq* polymerases can increase the efficiency of the PCR reaction (Fratamico and Bales 2005), and fluorescent-labeled primers has been shown to lower detection limits. Chen et al. (1998) used fluorescent-labeled primers to detect STEC in foods. Primers were designed to detect the presence of the shiga toxin genes *stx1*, *stx2*, and *stxe*. Detection limits of the method

were 1-5 CFU per PCR mixture (pure culture), and 3 CFU per 25g of food. Fanning et al. (1995) used a similar approach to develop a color amplified PCR system to detect the heat stable toxin gene (ST) in enterotoxigenic *E. coli* (ETEC). The method was found to have a lower detection limit of 10 fg of purified DNA and was capable of detecting 270 CFU of an ETEC strain possessing the ST gene.

Niessen (2008) described the use of PCR for the diagnosis and quantification of mycotoxin-producing fungi in foods and other commodities, while Zhang et al. (2008) reported a modification of PCR using an immuno-PCR assay for the detection of shiga toxin 2 (*stx2*) in culture which reduced the sensitivity to a level of 10pg/ml, when compared with commercial enzyme immuno assays which had a limit of detection of 1 ng/mL. Ge et al. (2002) used a combination of PCR with ELISA to detect STEC in food and found detection limits of the assay were 0.1–10 CFU, depending on the strain type. Another modification of PCR combined restriction fragment length polymorphism (RFLP) (Atanassova et al. 2001) for the detection of *S. aureus* and staphylococcal enterotoxins in pork and pork products. This method was found to be more sensitive than standard culture techniques with a detection rate of 28.6–34.8% compared to 11.1% by standard culture. Other modifications of PCR include restriction site specific PCR (RSS-PCR) (Kimura et al. 2000) and the ramification assay for detection of *E. coli* O157:H7 and STEC (Li et al. 2005).

Nested PCR

Nested PCR is a refined method for enhancing the specifics of PCR for pathogen detection. It uses a primary set of primers to amplify a specific region of DNA, then a secondary set of primers is used to amplify a product that lies (i.e., nested) within the initial product. Nested PCR is designed to increase the accuracy of the PCR reaction; that is, the dual amplification strategy ensures that if the wrong target is amplified in the primary reaction, the odds of a second successful amplification is low, as the second pair of primers are smaller and designed to amplify only within a region of the first PCR product. Therefore, the odds of amplifying such a product in an error sequence become low and the accuracy of the results are likely increased over standard methods. Nested PCR has been used in the detection of *Shigella* in food (Lindqvist 1999, Warren et al. 2006) and for the detection of toxin-associated genes in some pathogens. Miwa et al. (1996) described the use of nested PCR for the detection of enterotoxigenic *Clostridium perfringens* in animal feces and meat using a pair of nested primers homologous to the *C. perfringens* enterotoxin gene. The sensitivity of the test was about 10^3 fold greater than standard PCR.

Real-time PCR

Real-time PCR is a modification of conventional PCR that eliminates the need for gel electrophoresis, thus providing the user results more quickly. A recent review by Mackay (2004) provides

good information into the detail of the technology. Whereas, its underlying principle is based on standard PCR, a fluorescent tag is added to the primers so that the amplicons can be detected on a real-time basis by monitoring fluorescence. Thus, a detector in the thermocycler detects amplified product as it is produced. Real-time PCR protocols can be designed to detect multiple products simultaneously using a similar approach to multiplex PCR—typically, four or five fluorescent tags can be detected simultaneously as with conventional multiplex PCR. It also means that products of the similar size can be amplified easily without the challenges posed by separation on a standard electrophoresis gel, as each amplicon will be amplified with a different fluorescent marker. The advantages of real-time PCR over conventional PCR include: easy resolution of product, a faster run time as there is no post-PCR gel analysis, and increased sensitivity. The latter is greater than conventional PCR, as real-time PCR technology relies on the detection of a signal and its quantification with the release of light being in proportion to amplified product formed. Fluorescent dyes such as HEX, FAM, ROX, and SYBR green are some of the commonly available fluorescent dyes, which can be used simultaneously in a multiplex real-time-PCR protocol (Huang et al. 2007, Wang et al. 2007, Nde et al. 2008b). Multiple commercial thermocyclers are available for use in performing real-time PCR offering capabilities from single tubes to 96 and 384 well formats and have the capability to detect up to five different fluorescent targets simultaneously. Despite the practical advantages of this method, the expense of the requisite thermocyclers is high that may curtail the use of real-time PCR in some instances. Potential applications of real-time PCR include detection of genes or strains in a range of media (Rodriguez-Lazaro et al. 2004, Fakhr et al. 2006, Bohaychuk et al. 2007, Wang et al. 2007, O'Grady et al. 2008), and diarrheagenic *E. coli* (Vidal et al. 2005). Horsmon et al. (2006) used real-time fluorogenic PCR to detect *entA*, encoding the staphylococcal enterotoxin A (SEA). The method detected SEA at levels as low as 1–13 gene copies. Fykse et al. (2007) used molecular beacon real-time nucleic acid sequence-based amplification for *Vibrio cholerae* by detecting the cholera toxin gene (*ctxA*) and the genes *tcpA*, *toxR*, *hlyA*, and *groEL* and was able to detect the organism at a level of 50 CFU/mL, the method could also differentiate toxigenic from nontoxigenic *Vibrio* strains by amplification of the toxin genes *tcpA* and *ctxA*. Grant et al. (2006) modified the real-time PCR technique to simultaneously detect heat stable and labile toxin genes of enterotoxigenic *E. coli* with threshold cycles of 25.2–41.1.

A primary limitation of PCR has been that it could not distinguish between live and dead cells. However, newly designed PCR protocols can target viable cells by detection of mRNA, which is a marker of viability (Klein and Juneja 1997, McIngvale et al. 2002, Morin et al. 2004).

Overall, PCR has tremendous power as a molecular detection and profiling tool especially as a means to detect a pathogen as well as determine a pathogen's traits or to define its pathotype. It can also be useful for clustering gene traits and can provide significant information when bundled with analysis software to sort organisms into cluster groups or by trait possession (Rodriguez-Siek et al. 2005a, 2005b).

NEXT-GENERATION TECHNOLOGIES

The application of sensitive and rapid detection technologies has become of paramount interest in advancing methods for rapid detection and identification of pathogens of concern. In this section, we review some of the newer technologies emerging for the future and their potential for enhancing methods to detect foodborne pathogens. As we write this section, however, the reader should be aware that the technology is rapidly changing, some recent reviews in relation to the use of biosensors include articles by Kaittanis et al. (2010), Tallury et al. (2010), and Velusamy et al. (2010). Two of the overriding factors in sensor detection methodologies are the ability to obtain a result in a faster time frame and a preference to automate the system (Anderson and Taitt 2005). Biosensors are detection devices that use biological molecules to recognize and quantify analytes of interest—these analytes include antibodies, receptors, enzymes, nucleic acids, oligosaccharides, peptides, and so on. A recognition event between a biomolecule and an agent (e.g., nucleic acid, receptor, and so on) results in an output that can be measured either optically, chemically, or electronically. Biosensors should be able to monitor a sample continuously for analyte and provide a quantitative readout (such as measure of concentration).

ADENOSINE TRIPHOSPHATE DETECTION

Although not a strict biosensor per se, detection of adenosine triphosphate (ATP) from living cells is used as a means to assess the quality of cleaning or disinfection of surfaces and utensils. ATP detection usually involves analysis of a sample swab of an area; the swab is then combined with a mixture of the enzyme luciferase and its substrate luciferin. The reaction of luciferin and luciferase is dependent on the presence of ATP to catalyze the reaction, which is only found in living cells. The ATP combines with luciferin to form luciferyl adenylate and pyrophosphate.

$$\text{Luciferin} + \text{ATP} \rightarrow \text{Luciferyl} + \text{PP}_i$$
The luciferyl adenylate reacts with oxygen to form oxyluciferin and adenosine monophosphate with the release of light.

$$\text{Luciferyl adenylate} + O_2 \rightarrow \text{Oxyluciferin} + \text{AMP} + \text{Light}$$
The enzymatic process results in the release of light, which can be measured and is proportional to the amount of ATP present. There are a number of handheld devices that can be used for this type of testing and are available commercially. Typical levels of detection are 1–200 CFU. ATP assays are nonspecific and in general provide information of a quality nature; it cannot detect for specific pathogens or identify the source of ATP and typically are used as an indicator of hygiene quality or successful sanitization. In addition, the system may have errors associated with the sampling technique resulting in false-positives and false-negatives (Carrick et al. 2001). Modifications of ATP detection have incorporated the use of fluorescence for

detection of fluoroimmuno-stained cells; bioluminescence with IMS (Takahashi et al. 2000, Tu et al. 2000, Squirrel et al. 2002).

DNA Microarrays

DNA microarrays consist of gene probes arrayed on a substrate. Such arrays may be limited to select genes of interest or be multigenome-wide in scope. Among other things, they can be used for comparative genomic hybridization (also called genotyping), to study genome-wide gene expression or for the detection of pathogens in a sample. They have quickly become a powerful tool in genomic analysis of pathogens. The microarray itself (often called a gene chip or biochip) consists of a series of DNA molecules of known sequence called probes that are fixed to a substrate (usually, a special type slide). These probes consist of partial gene sequences, generated from PCR, full-length cDNA, or oligonucleotides (Pagotto et al. 2005) of the pathogens of interest. Such microarrays can be used to detect a large number of pathogens in a sample or alternatively, they can be used to perform expression studies of the whole genome or select genes; for the purposes of this chapter we will focus on the use of microarrays as a detection technology only; for more detail regarding other applications of microarrays the reader is directed to reviews on the subject. A recent review by Ojha and Kostrzynska (2008) highlights the application of microarray technology in the field of veterinary research for pathogen infection investigations, diagnostics, and studies of host pathogen interactions. Similar research by Jin et al. (2005) used microarray technology to investigate *E. coli* O157:H7.

Microarrays can also be used to assess similarities between strains, characterize strains or subtype strains. Boyd et al. 2003, Gaynor et al. (2004), Hain et al. (2006), Malik-Kale et al. (2007), Parker et al. (2007), and Raengpradub et al. (2008) have described the use of microarray technology to analyze strains at the genetic level for comparative purposes. Volokhov et al. (2002), (2003), Chen et al. (2005), Reen et al. (2005), Garaizar et al. (2006), Anjum et al. (2007), Yoshida et al. (2007), Zhang et al. (2007), Batchelor et al. (2008) have used microarrays to identify various bacteria to species or subspecies level, detection of virulence or antimicrobial resistance genes and Call et al. (2001), Chandler et al. (2001), Keramas et al. (2004), Kostrzynska and Bachand (2006), Kostic et al. (2007), Quinones et al. (2007) have used them for detection, identification, and characterization of pathogens in a range of samples. Given the unlimited amount of information available, microarrays can be designed and built for a range of purposes such as, determining expression of specific virulence or antimicrobial resistance genes or for more specific processes, such as study of invasion, flagellar production, growth processes, or biofilm production. DNA microarrays offer much promise for future studies in understanding pathogens, hosts, and production systems—they can be used to model host–pathogen interactions and the effect of various drugs or vaccines on a host or pathogen. Therefore, it is likely that microarray technology will provide needed insight into faster methods for detection and understanding the mechanisms of pathogenesis used by food-borne pathogens that can be exploited to make food safer.

Immunosensors or Biosensors

Biosensors are analytical devices that convert a biological response into an electrical signal. Biosensors work on the principle of a biological component that is coupled to a physiochemical type transducer that collects signal and converts it to an electronic readout. A range of bioreceptors currently recognized for use in pathogen detection include antibodies, enzymes, nucleic acids, cellular, biomimetic, and bacteriophages (Velusamy et al. 2010). Biosensor technology has rapidly expanded in the last 10 years and as this chapter is completed, there will no doubt be many more new applications emerging. Some of the more promising technologies at this point are based on fiber optics and electrochemical reactions. Velusamy et al. (2010) provide a comprehensive overview of sensors for application in pathogen detection.

Fiber Optic Biosensor

Optical fibers for the detection of pathogens work on the principle of a fiber optic taper that sends excitation laser light to a detection surface and receives emitted light. As such, fiber optic technology has been reported to be very useful in the detection of food-borne pathogens. Optical biosensors measure changes in refractive index, fluorescence emission or quenching, chemiluminescence, and fluorescence energy transfer. One such fiber optic biosensor operates by using an antibody sandwich format on optic fiber to detect the capture of antigens using fluorescently tagged conjugates. Geng et al. (2004) used a fiber optic-based detection system to detect *Listeria* in mixed cultures, and meat sample enrichments with a detection level as low as $10–10^3$ cells/mL. In a similar type approach, Kramer and Lim (2004) developed a rapid automated fiber-based biosensor for the detection of *Salmonella* in sprout rinse water. The sensor was capable of detecting *Salmonella* when counts as low as 50 CFU/g were inoculated into the seeds. Fiber optics have been used in *Listeria*, *Salmonella*, *E. coli* O157:H7, and *Clostridium botulinum* toxin detection (Ogert et al. 1992, Strachan and Gray 1995, Simpson and Lim 2005, Ko and Grant 2006) and for the detection of *S. aureus* (Chang et al. 1996).

Raman and Fourier Transform Spectroscopy

This technology is frequently used in whole organism fingerprinting but also has application in analysis of a sample of interest. The technique does, however, depend on increasing the population so that there is sufficient amount for biomass analysis. Raman spectroscopy is an optical technique that uses light scattering to detect pathogens (Schmilovitch et al. 2005). Modifications of Raman spectroscopy using surface enhanced technologies (Grow et al. 2003, Kalasinsky et al. 2007) have also been developed (see below).

Fourier Transform Infrared Spectroscopy

Fourier transform infrared spectroscopy (FTIR) is a nondestructive technique for pathogen detection that measures infrared loss

after passing through a sample, the data collected is analyzed using Fourier transformation and the resulting output results in a spectrum identical to the conventional infrared spectroscopy. FTIR has been used to differentiate and quantify *Salmonella*, *E. coli* O157:H7, and *Listeria* in various media or substrates (Lin et al. 2004, Yu et al. 2004, Al-Holy et al. 2006). Ellis et al. (2002) reported the use of FTIR directly on food to detect unique biochemical fingerprints of pathogens and provided a measure of bacterial loads.

Surface Plasmon Resonance

Surface plasmon resonance (SPR) uses reflectance spectroscopy to detect pathogens. The principle of the technique is based on the technology being able to detect minor changes in refractive index, which occur as cells of the target bind to receptors immobilized on a transducer surface. Changes in the angle of reflected light are measured as a function of changes in density of the medium versus time. SPR sensors have been used by a number of researchers for the detection of a range of pathogens including *L. monocytogenes*, *Salmonella*, *E. coli* O157:H7, and *C. jejuni* (Koubova et al. 2001, Bokken et al. 2003, Bhunia et al. 2004, Leonard et al. 2004, Meeusen et al. 2005, Subramanian et al. 2006, Taylor et al. 2006, Waswa et al. 2007).

SPR technologies use antibodies that are immobilized on a gold electrode surface that can measure miniscule changes in resonance frequency as a result of antibody antigen binding occurring (Feng 2007). Su and Li (2004) incorporated SPR with a piezoelectric system for the detection of *E. coli* O157:H7 at levels ranging from 10^3 to 10^8 cells; a similar approach by Oh et al. (2004) could detect *S. typhimurium* at levels ranging from 10^2 to 10^9 CFU/mL and Leonard et al. (2004, 2005) report detection of 10^5 cells/mL of *L. monocytogenes* in less than 30 minutes. Oh et al. (2004) report the development of an SPR chip capable of detecting multiple organisms simultaneously including *E. coli* O157:H7, *S. typhimurium*, *Legionella pneumophila*, and *Yersinia enterocolitica*.

Mass Sensitive Biosensors

Mass sensitive biosensors work on the principle of detection of minute changes in mass. The analysis depends on the use of piezoelectric crystals that vibrate at a specific frequency, as a result of electrical input at the same frequency. The frequency depends on electrical input and the mass of the crystal. If the mass of the crystal increases due to binding of agents, the weight of the crystal will change and therefore the oscillation frequency. The difference in oscillation results in a change, which can be measured electronically. Quartz is one of the most common piezoelectric material and the main types of sensors are quartz crystal microbalance (QCM) or surface acoustic wave (SAW). When the surface of the sensor is coated with an antibody and exposed to liquid containing the target pathogen—the pathogens will bind to the antibody resulting in a change in the weight of the crystal, and a shift in its frequency oscillation. QCM have been used in the detection of *Salmonella* (Su and Li 2005), *L. monocytogenes* (Vaughn et al. 2001), and *E. coli* O157:H7 (Berkenpas

et al. 2006). Modifications of the microbalance principle include piezoelectric excited millimeter sized cantilever and magnetoelastic sensors (Ruan et al. 2004, Mutharasan and Campbell 2008).

Electronic Nose Sensors

Electronic nose technology for pathogen detection works on the principle of detection of volatiles produced by active organisms in a food sample. The system is based on adsorption of volatiles to a series of conducting organic polymers; once the volatiles are adsorbed there is a change in the resistance of the sensors that can be equated to the presence of an organism or a population of organisms. Balasubramanian et al. (2005) used a commercial electronic nose system to detect *Salmonella* in inoculated beef samples. The system was able to differentiate *Salmonella* contaminated from noncontaminated meat. Similar systems have also been used in the detection of *E. coli* O157:H7 Younts et al. (2002, 2003) assessed the use of gas sensors for detection of *E. coli* O157 and non-O157 strains. Sensitivity and specificity ranged from 41.7 to 50% for nonnormalized data, which contrasted to data normalized using artificial neural network (ANN) classification that increased sensitivity from 91.7% to 100% but specificity ranged from 37.5% to 50%. Magan et al. (2001) used a commercial system for detection of *Pseudomonas* and *Bacillus* species in milk; Muhamed-Tahir and Alocilja (2003) developed a portable sensor system for detection of *E. coli* O157:H7 with a minimum detection limit of 7.8×10^1 CFU/mL. Arshak et al. (2009) used a series of conducting polymers to detect a range of food-borne pathogens including *Salmonella*, *Bacillus cereus* and *Vibrio parahaemolyticus*, and was able to differentiate each based on its signal.

Nanotechnology for Pathogen Detection

As one of the latest technologies, nanotechnology presents a great opportunity for rapid detection, diagnosis, and identification of pathogens. Nanoparticles, in particular, gold and silver have electronic and optical properties that make them useful in next generation detection. When the particles are coupled to affinity ligands they can be useful in pathogen detection; for example, gold nanoparticles coupled with specific oligonucleotides can detect complementary DNA. Other types of nanoparticles including quantum dots and carbon nanotubes have been used in assays for detection of pathogens, toxins, DNA, and in immunoassay development (Kaittanis et al. 2010). Recent articles by Kaittanis et al. (2010) and Tallury et al. (2010) provide some interesting overviews of nanotechnology applications in pathogen detection.

SUMMARY

Pathogens associated with human disease are constantly changing, what was old is now new and what was new has emerged in new ways not previously recognized as a means to cause disease. As fast as the pathogens are emerging, technologies and applications for their detection have become the next race to find the

ultimate technology that can detect all in a user-friendly manner, in as short a time as possible and with the ultimate sensitivity and specificity.

Biosensors for Sensitive Detection of Agricultural Contaminants, Pathogens and Food-Borne Toxins

Barry Byrne, Edwina Stack, and Richard O'Kennedy

Abstract: Immunosensors permit the rapid and sensitive analysis of a range of analytes. Here, we provide a critical assessment of how such formats can be implemented, with emphasis on the detection of bacterial and fungal pathogens, agricultural contaminants (e.g. pesticides and herbicides) and toxins.

INTRODUCTION

The monitoring of quality of food destined for human consumption is a key consideration for farmers, the food industry, legislators and, most importantly, for consumers (Karlsson 2004). Hence, it is an absolute necessity to ensure that any contaminants that may have a deleterious effect on human health are monitored qualitatively and quantitatively in a sensitive and reliable manner. For example, herbicides and pesticides are extremely effective at suppressing the growth of plant and insect populations on agricultural produce, such as tomatoes and strawberries. However, the extensive use of such potentially toxic compounds may compromise the quality of the product, and prolonged exposure may manifest itself as chronic toxicity in human hosts (Keay and McNeil 1998). Furthermore, bacterial strains such as *Salmonella typhimurium* and *Listeria monocytogenes*, which are causative agents of salmonellosis and listeriosis, respectively, can act as opportunistic pathogens and cause death through the ingestion of contaminated produce. Consequently, the development of suitable methods for their rapid detection is an absolute necessity. Finally, there is also an urgent need to accurately monitor the distribution of toxins, including fungal (e.g. mycotoxins) and water-borne toxins (e.g. phycotoxins), which cause severe illness through the consumption of contaminated food (e.g. nuts, shellfish meat). In summary, rapid, sensitive and accurate methodologies are essential for the evaluation of product quality and for satisfying legislative requirements.

CONTAMINANT MONITORING

TRADITIONAL MEANS OF ASSESSMENT

There are several standard methods that are currently used to monitor the quality of food. As an example, fruit and vegetable produce may be inspected by monitoring the colour, gloss, firmness, shape and size of the product, as well as noting the presence or absence of visible defects. This visual inspection may be performed alongside more invasive methods, including the analysis of the soluble solid content of the product and determining the acidity, and is particularly useful for produce such as apples, pears and berries. The main advantage of such tests relates to the fact that they may be carried out immediately post-harvest

by the farmer, and at a minimal cost (Mitchum et al. 1996). As further examples, grain and nuts may be inspected for the presence of fungal contamination, while bacterial spoilage may be indicated by the presence of an uncharacteristically strong odour, such as in coleslaw and milk. However, these tests are not sufficient for providing confirmation to the consumer that the product satisfies regulations with respect to acceptable maximum residue limits (MRLs). Furthermore, it is not possible to provide accurate quantitative or qualitative analysis of individual contaminants through these methodologies, including those that cannot be seen by visual inspection (e.g. mycotoxins). Hence, it is common practice for food samples to be removed and sent to an external laboratory where comprehensive in situ analysis may be performed (Giraudi and Baggiani 1994).

INSTRUMENTATION-BASED ANALYSIS

There is a selection of different methodologies available for quality determination, and some of the more relevant examples are discussed in this section. Product firmness can be determined through the implementation of the Magness-Taylor test, namely a destructive method that assesses the maximum force required to perforate the product in a specific way (Abbott 2004). This has been applied for the analysis of fruit, including pears (Gómez et al. 2005). The non-destructive determination of elasticity may also be permitted through the measurement of acoustic responses, with the signal being interrogated using fast Fourier transform-based analysis. Shmulevich et al. (2003) demonstrated the efficacy of this approach for evaluating the firmness of apples, and monitored product softening over time in a controlled atmosphere environment. While these methods are suitable for monitoring the structural properties of the product in question, they do not permit rigorous quality evaluation.

More suitable analytical methods include near-infrared (IR) spectroscopy, implemented by Berardo et al. (2005) for the detection of mycotoxigenic fungi and associated toxic metabolites, and scanning electron microscopy, applied for the inspection of ultrastructural changes of the epicuticular layer of oranges

treated with fludioxonil, a pesticide used to control the growth of two *Penicillium* species (*Penicillium digitatum* and *Penicillium italicum*) (Schirra et al. 2005). Furthermore, gas chromatography (GS) or mass spectrometry (MS) and high-performance liquid chromatography (HPLC) are accurate and highly sensitive methods for the detection of an array of contaminants, including pesticide, herbicide and toxins residues. The latter method may also be used to detect the presence of indicator molecules that are representative of product freshness, including flavonoids (MacLean et al. 2006), while liquid chromatography coupled with mass spectrometry (LC-MS) can accurately monitor product bitterness. This was demonstrated by Dourtoglou et al. (2006) for the analysis of olives (*Olea europaea*). In spite of the efficacy of these analytical platforms, the instrumentation needed to perform this analysis is expensive and bulky and may require extensive operator training. In addition, analysis times may also be extensive, as many contaminants require lengthy sample pre-treatment prior to assessment.

Here, we focus on the application of biosensor-based platforms that are rapid, sensitive and reliable and are frequently used for the detection of herbicide and pesticide residues, bacterial and fungal pathogens and toxins (fungal and water-borne).

BIOSENSORS

A biosensor can be defined as an analytical device that incorporates a biological element for promoting biorecognition of an analyte of interest (e.g. herbicide, bacterial cell or toxin). A schematic representation of a biosensor, illustrating the three main components of the system, namely a bioligand, a transducer and a readout device, is shown in Figure 45.1. Biosensor-based platforms can use a wide selection of different recognition elements, including nucleic acid probes, lectins and antibodies (Table 45.1). The focus in this chapter will be placed on the use of antibodies for detection of contaminants that are of interest to the food industry with examples of enzyme- and nucleic acid-based detection also provided.
Figure 45.1. General format of a biosensor. The biorecognition element is in contact with the transducer, which converts the signal to an output shown on the computer. For illustrative purposes, an antibody-based platform is shown, with non-specific antigens represented by squares and triangles, respectively.

Table 45.1. The Recognition Elements Commonly Used in Sensor Systems

1. Antibodies and antibody fragments: Derived by enzyme digestion or genetic engineering (Fab fragment, scFv and diabody).
2. Lectins, namely carbohydrate-binding proteins. Only suitable for the detection of glycosylated entities, such as glycoproteins.
3. Enzymes: e.g. those specific for one particular substrate (i.e. horseradish peroxidase for hydrogen peroxide).
4. Cell membrane receptors.
5. A living cell: eukaryotic or prokaryotic.
6. Nucleic acid-based probes: DNA and RNA or peptide nucleic acid.
7. Aptamers.
8. Chemically generated recognition surfaces: Including plastibodies (artificial antibodies or molecularly imprinted polymers).

Fab, fragment antigen binding; scFv, single-chain variable fragment.

A transducer is a device, such as a piezoelectric crystal or photoelectric cell that converts input energy of one form into output energy of another, with the output signal generated proportional to the concentration of the target analyte (Luong et al. 1995). There are many different types of transducers that can be used in biosensor-based platforms, and a selection of these is shown in Table 45.2. Finally, a readout device typically consists of a computer-linked monitor that presents the data in a form that can easily be interpreted by the end-user.

Many different biosensor platforms have dedicated software packages that can facilitate in the interpretation of biomolecular interactions. For example, Biacore, a frequently used commercial optical biosensor based on surface plasmon resonance (SPR), which is discussed in more detail later, uses Biaevaluation software that presents data in the form of a sensorgram (Fig. 45.2). Here, interactions between immobilised and free entities can be easily visualised by monitoring changes in refractive index (RI). This correlates to a change in mass imparted by the interaction between the two binding elements (e.g. antibody and cognate antigen), with units of measurement referred to as response units (RU). In Biacore analysis, a response of 1000 RU is representative of a change in resonance angle of $0.1°$, which corresponds to an alteration in the surface coverage of the sensor surface of approximately 1 ng/mm^2.

While Biacore is an excellent example of a biosensor that is commonly used for the evaluation of quality of food (which is discussed in more detail later) other biosensor platforms are also applicable that are based on electrochemical, piezoelectric, magnetic and thermal detection (Byrne et al. 2009). Many of these platforms are developed 'in-house' and have their own dedicated software packages for the interpretation of data, and key examples of these novel sensors are also described later. Finally, for a biosensor to be applicable in any field, including in the monitoring of quality of food produce, it must have certain characteristics. These are listed in Table 45.3.

BIACORE

Biacore (GE Healthcare) uses an optical-based transducer system for the measurement of analytes based on the principle of SPR. SPR works on the principle of total internal reflection (TIR), a phenomenon that occurs at the interface between two non-absorbing materials, such as water and a solid. When a source of light is directed at such an interface from a medium with a higher RI to a medium of lower RI (such as light travelling through glass and water), the light is refracted to the interface

Table 45.2. Examples of Transducers Commonly Used in Biosensor Systems

Type	Example	Principle of Use
Electrochemical	Conductimetric	Solutions containing ions conduct electricity. Depending on the reaction, the change in conductance is measured.
	Potentiometric	Measurement of the potential of a cell when there is no current flowing to determine the concentration of an analyte.
	Voltammetric	A changing potential is applied to a system and the resulting change in current is measured.
Field effect transistor-based	Field effect transistor	A current flows along a semi-conductor from a source gate to a drain. A small change in gate voltage can cause a large variation in the current from the source to the drain.
Optical	Surface plasmon resonance	Surface plasmon resonance (a detailed explanation is given in this chapter).
Thermal	Calorimetry	Heat exchange is detected by thermistors and related to the rate of a reaction.
Surface acoustic wave	Rayleigh surface wave	An immobilised sample on the surface of a crystal affects the transmission of a wave to a detector.
Piezoelectric	Electrochemical quartz crystal microbalance	A vibrating crystal generates current that is affected by a material adsorbed onto its surface.

Figure 45.2. Schematic representation of a Biacore sensorgram, which provides information relating to the biomolecular interaction between the immobilised antibody and its cognate antigen (relevant analyte).

Table 45.3. The Ideal Characteristics of a Biosensor

1.	The biorecognition element must be highly specific for the substrate or antigen.
2.	Re-usable, with multiple readings permitted on a single device.
3.	High sensitivity.
4.	Cost-effective.
5.	Permit rapid or 'real-time' analysis of biomolecular interactions.
6.	Use of 'on-line' or 'in-situ' measurement.
7.	Good signal to noise ratio.
8.	The device should be robust.
9.	The ability to measure samples in a high throughput fashion, if required.
10.	Fast turnaround time on analysis.
11.	Ease of use.

more recently developed A100, permit high-throughput analysis of protein–protein and protein–ligand interactions that may be useful in the judicious selection of antibodies for specific diagnostic applications.

SENSOR SURFACES

When selecting a biosensor-based platform, such as Biacore, for the evaluation of quality of food produce, several key considerations should be made. The first of these relates to the nature of the analytical surface that will be used in the assay. One of the primary reasons why Biacore is commonly selected for food analysis (aside from the excellent sensitivity and flexibility for designing a suitable assay) relates to the fact that many different surface chemistries are available for conjugating molecules onto the sensor chip surface to perform the assay. Biacore uses sensor chips, such as those mentioned in Table 45.4, and the choice of chip chemistry is dependent on a number of different factors, including the desired application of the assay, the physical and chemical properties of the binding partners and the nature of the biomolecular interaction.

The CM5 chip is the most versatile Biacore chip currently available and is the most frequently used for food analysis. Its matrix consists of a completely modified carboxy-methylated dextran covalently attached to a gold surface, and is ideally suited for the analysis of a variety of different binding events, ranging from those involving small organic molecules to multi-domain proteins. Analytes of interest can readily be coupled to the sensor chip surface through the application of a number of different cross-linking chemistries (e.g. amine, thiol or aldehyde coupling), and a stable surface can be produced that permits accurate and repeated analysis on a single surface (Dillon et al. 2005) as non-covalently bound entities can readily be removed from the surface by a process termed regeneration. Typically, this is achieved with low concentrations of acid (HCl) or base (NaOH). As an example, for the detection of a bacterial strain in a complex sample matrix (e.g. coleslaw), a pathogen-specific antibody may be immobilised on a CM5 surface by amine

(Markey 2000). However, when the light is above a particular angle of incidence, no light is refracted across the interface and TIR occurs. Even though the incident light is reflected back from the interface, an electromagnetic field (called an evanescent wave) penetrates a distance of the order of one wavelength travelling into the less optically dense medium.

A key advantage of SPR over other optical methods of detection is that SPR measures the interaction between immobilised molecules on a surface (e.g. an antigen, or an antibody immobilised onto a sensor chip) and the corresponding ligand in solution passing over this matrix. This means that the reaction can be measured in a coloured solution or in a turbid complex matrix, such as in fruit juice or vegetable preparations. Hence, there is no requirement for food samples to be pre-treated to remove contaminating coloured species prior to analysis.

The Biacore system has a lower limit of detection (LOD) of approximately 10 RU (which is approximately 10 pg/mm^2), which is suitable for the detection of trace amounts of analytes of interest, such as pesticide or herbicide residues. There are several platforms available for use. The Biacore Q instrument has major potential for quality control analysis, whereas the Biacore 3000 is particularly useful for high sensitivity antibody-based analyte detection and kinetic analysis. The T100 and the

Table 45.4. The Surface Chemistries of Available Biacore Chips

Chip Type	Modification Type	Applications
CM5	100% carboxylation of dextran surface.	General use. Routinely selected for antibody-antigen and protein-protein interaction analysis.
CM4	30% carboxylation of dextran surface.	Serum, cell extracts.
CM3	100% carboxylation of dextran surface.	Serum, cell extracts.
C1	100% carboxylation of dextran surface.	Permits binding events to occur closer to the sensor surface, which is advantageous in situations where multivalent interactions occur, or where analytes are large.
L1	Lipophilic.	Lipid capturing.
SA	Streptavidin surface.	Detection of biotin-containing molecules. Useful for immobilisation.
NTA	Nickel – nitrilotriacetic acid.	Detection of histidine-tagged molecules.
HPA	Flat hydrophobic surface.	Used for membrane-associated interactions.
Au and SIA	None.	Useful for self-assembled monolayer-based interactions analysis.

coupling. This covalently captured immunoglobulin may then be used as a bioligand to capture the pathogen from the food sample, which is injected over the sensor surface and, therefore, is in solution. The change in mass resulting from the biomolecular interaction introduces a change in RI, as seen by an increase in RU, and regeneration can subsequently be used to liberate the bacterial cell(s), so that the immobilised antibody is available for subsequent analysis. This method of analysis can be used for detection purposes and can be used to establish LODs. Furthermore, where required, kinetic analysis can be used to determine the affinity of the antibody for its cognate antigen.

ASSAY CONFIGURATION

For food-based biosensor analysis, analytes of interest range in size from large (intact bacterial and fungal cells) to small (pesticide and toxin residues), requiring that the assay format selected must be capable of providing accurate and quantitative detection. Biacore-based assays that monitor interactions between large biomolecules, such as antibodies and proteinaceous antigens, can be developed by immobilising either the antibody or antigen on the surface, as the mass change introduced by the binding of the other entity is sufficient to cause a recordable change in RU that can be seen on a sensorgram. However, as contaminants such as herbicides, pesticides and toxins have low molecular weights, it is often necessary to employ an indirect measurement method where the analyte is immobilised directly on the sensor surface, and the larger of the binding elements is subsequently introduced. The resultant change in mass introduced by the binding of the larger element (in solution) to the smaller, immobilised ligand can therefore be easily seen as a change in RU. If the assay was to be performed in reverse (e.g. the larger entity is immobilised and the small hapten or toxin is free in solution), a small change in mass would be introduced during an interaction event, which may be difficult to detect and quantify reliably.

Many of the examples that are discussed in this chapter employ antibody-based competition or inhibition assay formats (Fig. 45.3). An inhibition assay involves the combination of the sample of interest with the specific antibody before injection onto a biosensor chip containing an immobilised target molecule. There is competition between the immobilised and free antigen (from the sample to be analysed) for antibody binding. A change in signal (e.g. RU) is recorded, and this is inversely proportional to the amount of target analyte that remains free in solution. An alternative method to detect analytes of interest requires a competitive assay format. In this format, the antibody, specific to the analyte of interest, is immobilised on the surface. The sample, containing the analyte to be determined, is mixed with a known concentration of standard consisting of the target analyte that has been conjugated to a large carrier protein. This results in the analyte and the conjugated standard competing for the immobilised antibody on the surface of the biochip. An increase in signal is caused by the binding of the large analyte-carrier conjugate and the data generated are similar to the inhibition assay since the signal recorded is inversely proportional to the amount of target analyte present in the sample. However, to perform these assays, it is necessary to have a suitable antibody, and methods for antibody production are discussed in Section 'Antibody Production Strategies'.

ANTIBODIES

Antibodies are the key biorecognition elements of the immune system. A large variety of antibodies and antibody-derived fragments have been produced with the capability of detecting an array of structurally diverse analytes, ranging from proteins to haptens, and these have been implemented in a number of different biosensor formats. Antibodies are globular glycoproteins (sugar-containing proteins), and five main classes (or serotypes) exist in nature, namely IgA, IgM, IgE, IgD and IgG. Single antibody molecules typically have molecular weights of approximately 150–200 kilodaltons (kDa). IgG antibodies (Fig. 45.4) have a Y-shaped backbone with four polypeptide chains located in two identical chains that are covalently attached through disulphide bonds. The innermost chains are referred to as the heavy chains because they are approximately double the molecular weight of the outer arms (termed the light chains). The
Figure 45.3. Formats for inhibition and competition assays. For illustration, a Biacore surface is represented.
Inhibition: Free analyte inhibits binding of the antibody to the immobilised analyte on the chip. The signal generated when the antibody binds to the immobilised analyte is inversely proportional to the concentration of free analyte in the sample.

Competition: Free (●) and conjugated ( ) analyte compete for binding to the immobilised antibody. The signal generated is inversely proportional to the amount of free analyte in the sample.
Figure 45.4. Structure of an IgG antibody. CH_{1-3} refers to constant heavy regions 1 to 3, respectively. V_H, variable heavy; V_L, variable light.

recognition sites of the antibody, which interact with an epitope on an antigen of interest, are located at the ends of the variable heavy (V_H) and variable light (V_L) regions of the heavy and light chains, respectively. They are commonly referred to as the complementarity determining regions, or CDRs. Each arm of an antibody can bind to one antigen, so one IgG molecule can theoretically bind to two antigens.

ANTIBODY PRODUCTION STRATEGIES

There are three main methods for generating antibodies that may be used in biosensor-based platforms for quality evaluation, and these are discussed in this section. Polyclonal antibodies are produced through the immunisation of animal hosts with a particular antigen. The immunogen is typically administered in the presence of a suitable adjuvant, which elicits an immune response in the host. Small molecules, such as toxins or haptens, may have to be conjugated to larger carrier molecules, such as bovine serum albumin (BSA), to enhance immunorecognition. Serum titres are typically analysed by enzyme-linked immunosorbent assay (ELISA) to quantify the host-based response. If this is deemed to be suitable, blood samples are subsequently collected and the antibodies generated are purified from the serum. Polyclonal antibodies typically consist of a variety of different serotypes with varying affinities/specificities towards the analyte in question. Animals often used for polyclonal antibody generation include guinea pigs, rabbits, goats, sheep and donkeys (Leenaars and Hendriksen 2005).

The second method involves the use of hybridoma technology to produce monoclonal antibodies (Köhler and Milstein 1975, Nelson et al. 2000, Hudson and Souriau 2003). These are generated by immunising an animal (typically, a mouse) with the antigen of interest in the presence of a suitable adjuvant. Once a sufficient immune response is detected by ELISA, the spleen, bone marrow from long bones (femur and humerus) or primary lymphoid organs (such as lymph nodes) are removed from the sacrificed animal and the antibody-producing B-cells are harvested. These cells can then be fused to immortal myeloma cells by using an electrical current or polyethylene glycol. The resulting hybrid cells (hybridomas), which secrete antibodies that are directed towards the desired antigen, are then selected and cloned out to ensure monoclonality. The advantage of this approach is that there is a constant supply of the antibody that is required for analysis. However, there is a significant cost involved in the production and the screening of these antibodies.

Recombinant antibodies are the third form of antibodies that are increasingly being used. They are often produced in bacterial strains such as *Escherichia coli* and are expressed in a phage display format. Libraries, with the capacity to express a large number of antibodies, are generated, and they are referred to as naive, synthetic or immune depending on their mode of production (Bradbury and Marks 2004). Immune libraries are constructed though the administration of the immunogen of interest to a suitable host (e.g. mouse, rabbit, chicken), which is monitored for antibody production. Antibody-encoding nucleic acid is then purified from lymphoid organs, such as the spleen, and cloned into a phage or phagemid vector that, in turn, is
Figure 45.5. Different antibody fragments available for biosensor-based analysis. CH_{1-3} refers to constant heavy region 1; V_H, variable heavy; V_L, variable light; scFv, single-chain variable fragment; Fab, fragment antigen binding.

propagated in *E. coli*. Phage display libraries can subsequently be screened against targets of interest by biopanning. This is feasible since the phage express the active recombinant antibodies on their surface and those that bind to the specific antigen immobilised on a capture surface can be differentiated from non-binding antibodies, and characterised further to determine their affinity for the target antigen. A key advantage with recombinant antibodies is the ability to increase their affinity for an antigen of interest through site-directed mutagenesis or other approaches such as chain shuffling or error-prone PCR, which is not possible for monoclonal or polyclonal antibodies (Conroy et al. 2009, O'Kennedy et al. 2010).

The main types of antibody fragments produced by phage display are the fragment antigen binding (Fab) and single-chain variable fragment (scFv), whose structures are shown in Figure 45.5. The presence of the constant regions in a Fab is thought to aid in the stabilisation of the antibody variable regions, which might not function efficiently when expressed in the monomeric scFv format (Röthlisberger et al. 2005). It was previously shown in our laboratory that the Fab antibody format is the most reliable and sensitive for use in small molecule competition biosensor assays involving haptens. The strict monovalency of this format can lead to a significant enhancement in assay sensitivity in both ELISA and competition SPR assays (Townsend et al. 2006).

The scFv is the most widely used antibody fragment. The variable regions (V_H and V_L) of the antibody are linked by a flexible peptide linker. The most frequently used are based on glycine-serine repeat structures, with the length of the linker related to the intended valency of the molecule. When a short linker is used, the stability and folding of the scFv does not occur properly. This is caused by the insufficient juxtaposing of the V_H and V_L regions in the single chain for the monomer to function. ScFvs selected in this format invariably form bivalent dimers, or diabodies, which often have increased avidity for an antigen over the monomeric forms typically observed when long-linker systems are used (Holliger et al. 1993, Kortt et al. 1997, Atwell

et al. 1999). Long linkers (ranging from 18–21 amino acids) favour the production of scFv formats, which are predominantly monomeric (Holliger et al. 1993, Perisic et al. 1994, McGuinness et al. 1996). In summary, recombinant antibodies are an excellent alternative to polyclonal and monoclonal antibodies for the detection of analytes of interest, and have great potential for application in the monitoring of quality in the food industry (Hudson and Souriau 2003, O'Kennedy et al. 2010).

OPTICAL IMMUNOSENSORS FOR QUALITY DETERMINATION

There have been several excellent examples of biosensor-based analysis for the detection of pesticides, herbicides, toxins and bacterial cells, and some of the more pertinent observations that employ antibody-based recognition (immunosensors) are discussed in this section. One of the earliest examples demonstrating the use of antibody-based biosensing for detecting herbicide residues was described by Minunni and Mascini (1993). Here, Biacore was selected as a platform to facilitate the detection of traces (50 pg/mL) of the herbicide atrazine in water samples. Another optical biosensor was developed to detect and quantify carbamate residues in vegetables. It was observed that changes in the concentration of carbamate could be monitored using chlorophenol red (Xavier et al. 2000). Moran et al. (2002) used SPR to characterise antibodies that were subsequently used to detect the presence of 2-(4-thiazolyl)benzimidazole, a molecule that is used as a food preservative and an agricultural fungicide. Schlecht et al. (2002) implemented a C1 four-channel sensor chip in a study to quantifiably detect the presence of 2,4-dichlorophenoxyacetic acid (2,4-D), an organochlorine herbicide, and monitor cross-reactivity of polyclonal antibodies with a structurally related analogue, namely 2,4,5-trichlorophenoxyacetic acid (2,4,5-T). This assay was permitted by immobilising 2,4-D analogues onto the surface of a C1 sensor chip surface through a thiol-carboxyl group reaction, and had a sensitivity of $0.1 \mu g/mL$. Finally, Caldow et al. (2005) used a Biacore Q instrument to detect the bacteriostatic antibiotic, tylosin, in bees' honey. This polyketide is active against most gram-positive bacteria, mycoplasma, and certain gram-negative bacteria. They were able to detect tylosin at the level of $2.5 \mu g/kg$ in honey, demonstrating the ability of biosensor platforms, such as Biacore, to detect analytes in complex sample matrices. These five key examples demonstrate early applications of using immunosensors for the detection of low-molecular weight analytes that have a deleterious effect on the quality of agricultural produce.

More recently, miniaturised biosensor platforms have been developed for in situ analysis of pesticide and herbicide residues. A portable immunosensor for the detection of 2,4-D was described by Kim et al. (2007). Here, murine hosts were immunised with a 2,4-D-BSA conjugate, and the resultant monoclonal antibodies were implemented for detection purposes. When tested on spiked river water samples, this assay format had excellent sensitivity (0.1 ppb of 2,4-D) and permitted the parallel analysis of multiple samples. This example also demonstrates how modification of the assay format can greatly improve sensitivity, which is a key

consideration for the detection of analytes, such as 2,4-D, which may reside in food or water samples in trace amounts. A sandwich assay format, incorporating a second biotinylated antibody, was subsequently developed whose sensitivity was significantly enhanced (0.1 ppt of 2,4-D).

Competitive and inhibition assay formats can be utilised effectively in a number of different biosensor formats for the detection of pesticide and herbicide residues. In some cases, this can be applied where the direct monitoring of the interaction between an antigen and its cognate antibody is not sufficiently sensitive. To illustrate this, Gouzy et al. (2009) developed a Biacore-based SPR competition assay for the detection of the herbicide isoproturon, as employing a direct detection assay was deemed to be inadequate. Here, a rat-derived anti-isoproturon monoclonal antibody was selected for biorecognition, and the competition assay had a good LOD ($0.1 \mu g/L$). Salmain et al. (2008) developed an indirect competition immunoassay format for the detection of atrazine. The biosensor format implemented was an IR optical platform that had nanomolar sensitivity.

Salmain et al. (2008) subsequently performed comparative sensitivity analysis in an ELISA-based assay format, and similar observations were made. ELISA assays are routinely selected for immunodetection purposes and, depending on the quality of the antibody, have excellent sensitivity. However, a major drawback relates to the fact that analysis times are often lengthy, with multiple incubation and washing stages required for assay completion. This is in contrast to biosensor-based assays that permit rapid analysis and facilitate the detection of multiple analytes on a single sensor surface, as opposed to using multiple wells. Therefore, ELISA formats may be initially used to validate an assay format before transferring this to a biosensor platform. This has been demonstrated by Herranz et al. (2008) for the evaluation of leporine polyclonal antibodies specific for simazine derivatives prior to their implementation in an immunosensor platform. The resultant assay had a LOD of 1.3 ng/L in contaminated water samples, and results were obtained in 30 minutes.

In the biosensor assay described by Herranz et al. (2008), it was also possible to monitor for cross-reactivity with other molecules, including structurally-related triazines (propazine and atrazine), and demonstrate the absence of non-specific binding to unrelated entities, such as 2,4-D. Biosensors permit rapid cross-reactivity analysis to be performed, where multiple analytes may be tested on a single antibody-immobilised surface. Alternatively, where small analytes are to be detected, numerous structural analogues may be immobilised on different surfaces (e.g. in a CM5 sensor chip, four individual flow cells are available) and tested with a panel of antibodies. This parallel immunosensing approach was recently demonstrated by Gao et al. (2009) for the detection of atrazine and four additional chemicals, namely paraverine, 17-β-estradiol, chloramphenicol and nonylphenol. The biorecognition elements implemented during this analysis were either monoclonal (anti-atrazine, anti-17-β-estradiol and anti-chloramphenicol) or polyclonal (anti-nonylphenol and anti-paraverine) antibodies generated in murine and leporine hosts, respectively. Optical biosensor-based platforms that can sensitively detect multiple contaminants, such as herbicide or pesticide residues, suggest the way forward for
Figure 45.6. Schematic diagram of an enzyme-transducer biosensor. When the redox enzyme goes through its catalytic cycle (going from an oxidised to reduced state and back to its resting state) the redox action of the enzyme is detected by the transducer and the change in electrical state is recorded as a change in the output signal. An electron is represented by e⁻.

monitoring the quality of agricultural produce. Furthermore, the possibility of translating these methodologies onto portable microdevices will permit 'on-site' analysis to be performed in a rapid, reliable and sensitive manner.

ELECTROCHEMICAL SENSORS

Electrochemical sensors have also been used extensively to detect analytes of interest in agricultural produce. These platforms are based on four different transducer types, namely amperometric, impedimetric, potentiometric and conductimetric (Conroy et al. 2009, Byrne et al. 2009). The biorecognition element in these sensors is in direct contact with a transducer, and the resulting signal that is generated is converted from a biochemical signal to an electrical signal. Similar to optical immunosensors, antibodies and enzymes are commonly used for biorecognition purposes. Enzymes that belong to the oxidoreductase class (enzyme classification (EC) 1) are frequently selected as they alternate between oxidised and reduced states that can be measured electrochemically and, therefore, can be exploited in these analytical devices.

Equation 1 illustrates the generation of an electron through the redox cycling of an enzyme. When the enzyme is located in close proximity to the surface of the transducer, electron transfer can occur directly (as shown in Fig. 45.6). However, as is the case with many naturally occurring enzymes, they are surrounded by a layer of carbohydrate or lipid. This increases the distance that electrons have to traverse, thus, causing a decrease in the signal recorded by the transducer. In situations where this occurs, electron mediators, such as ferrocene, are used (Fig. 45.7).
Figure 45.7. An enzyme-based electrochemical biosensor with an electron mediator. The mediator shuttles the electron (e⁻) from the enzyme to the surface of the transducer where it is converted from a chemical signal to an electrical signal. R and R′ represent the oxidised and reduced forms, respectively, of an electron mediator.

Table 45.5. The Ideal Characteristics and Properties of an Electron Mediator

1.	Exhibits reversible kinetics.
2.	Reacts readily with the reduced form of an enzyme.
3.	Has a low oxidation potential and is mediator activity is pH independent.
4.	Is stable in both redox forms.
5.	Easily retained at the surface of an electrode.
6.	Unreactive towards oxygen.
7.	Chemically unreactive with the immobilised biological material.

Table 45.5 illustrates the characteristics that are favourable in choosing a specific mediator (Cassidy et al. 1998).

Mediators are usually low molecular redox couples that shuttle the electrons from the enzyme's active site to the surface of the transducer. Equation 2 illustrates the reaction of the mediator and the subsequent generation of an electron resulting electrochemical cycling.

$$H_2O_2 + 2H^+ + 2e^- \rightarrow 2H_2O \tag{1}$$

$$Mediator_{red} \rightarrow Mediator_{ox} + e^- \tag{2}$$
Equations 3, 4, 5 and 6 illustrate a peroxidase-mediated reaction on a biosensor surface. Equation 3 shows the resting state peroxidase (in its reduced form) reacting with hydrogen peroxide and two hydrogen ions to form an intermediary oxidised-peroxidase compound and two water molecules. Equation 4 shows the reaction of the intermediary oxidised-peroxidase compound with the reduced form of a mediator to produce the resting reduced-state peroxidase and an oxidised mediator. Equation 5 shows the oxidised mediator reacting with two electrons, thus, reverting to the reduced form of the mediator. It is these electrons that the transducer detects and converts into an electrical signal.

The final Equation 6 shows the overall reaction, whereby one hydrogen peroxide molecule in the presence of two electrons and two hydrogen ions is converted to two water molecules (Ryan et al. 2006).

$$H_2O_2 + 2H^+ + PO_{red} \rightarrow PO_{ox} + 2H_2O \tag{3}$$

$$PO_{ox} + Mediator_{red} \rightarrow PO_{red} + Mediator_{ox} \tag{4}$$

$$Mediator_{ox} + 2e^- \rightarrow Mediator_{red} \tag{5}$$

$$H_2O_2 + 2e^- + 2H^+ \rightarrow 2H_2O \tag{6}$$
It is often possible to use a multi-enzyme electrochemical biosensor system to detect the presence and determine the concentration of a particular compound in a matrix of interest. This method employs two or more enzymes that are in proximity with each other and in contact with a mediator or directly in contact with the transducer. As illustrated in Figure 45.8, enzyme 1 (glucose oxidase (Gox)) generates hydrogen peroxide (H_2O_2) as a by-product through the catalysis of glucose by Gox. The H_2O_2 generated is catalysed by a peroxidase enzyme and the redox cycling of the mediator. The cycling of the peroxidase enzyme in the presence of H_2O_2 generates electrons that are detected by the transducer. This in turn enables the concentration of the target analyte to be determined, thereby providing quantitative determination.

There are several well-characterised electrochemical biosensor devices that have been applied in the fruit and vegetable industry for the detection of a number of structurally diverse compounds, including pesticides, herbicides, insecticides, organophosphates, organochlorines and carbamates. With reference to the detection of pesticide residues, there are many available options that can be implemented by the end user. More specifically, enzymes that are directly affected by the presence of a pesticide can be incorporated into a biosensor-based platform permitting detection (Amine et al. 2006). As an example, acetylcholinesterase (AChE) presents in muscles, red blood cells
Figure 45.8. A representation of a sensor with two enzymes operating together. The first enzyme catalyses the substrate of interest and, as a by-product, H_2O_2 is generated. This is then catalysed by a peroxidase enzyme. The redox activity of the peroxidase enzyme is detected by the transducer. Gox is glucose oxidase; H_2O_2 is hydrogen peroxide; R and R' represent the oxidised and reduced forms, respectively, of an electron mediator and e^- is an electron.

and nerve tissue, catalyses the hydrolysis of the acetylcholine, a neurotransmitter, to yield choline and acetic acid. This enzyme is associated with cognition in mammalian hosts. Compounds that effect AChE activity include organophosphates and parathion, which is routinely used as an acaricide and an insecticide. Botulinum toxin, produced by the bacterial strain *Clostridium botulinum*, also suppresses the release mechanism of AChE (Rang et al. 1998). The suppression of activity of this enzyme results in the accumulation of acetylcholine in the host, which can cause an excessive over-stimulation of the cholinergic nerves. Death usually results from the failure of the circulatory and respiratory systems (Timbrell 1991). Schulze et al. (2002) developed an amperometric AChE biosensor that was used for the detection of carbamate and organophosphate residues in a number of fruit-containing baby foods and fruit and vegetable samples taken from four different geographical locations. The protocol involved the printing of thick film electrodes onto sheets of polyvinylchloride and 'curing' for 30 minutes at 90°C prior to the introduction of AChE by glutaraldehyde coupling. The activity of AChE was analysed by monitoring the formation of thiocholine by the enzymatic hydrolysis of acetylcholine chloride. This sensor format permitted the detection of trace levels of these analytes (lower than 5 μg/kg), which included carbofuran, carbaryl and chlorpyrifos.

Wheat is a common component of food produce that should be monitored for the presence of pesticide residues. Del Carlo et al. (2005) quantified the amount of a phosphothionate insecticide (pirimiphos-methyl) present in durum wheat using an electrochemical biosensor. They used an AChE-inhibition assay and obtained a calibration curve between 25–1000 ng/mL with a detection limit of 38 ng/mL. When real samples of durum wheat were analysed, the LOD increased to 65–133 ng/mL, presumably because of the complexity of the sample matrix.

Cell-based biosensors that are also based on the inhibition of AChE are useful alternative formats for detecting chemical contaminants. Here, interactions between mammalian cells and chemicals, such as pesticides, are conducive to the disruption of cell membrane permeability, which can be quantified. To demonstrate how this assay format may be applied, Flampouri et al. (2010) recently prepared neuroblastoma and fibroblast mammalian cells by standard cell culture methodologies and immobilised these on a working electrode through entrapment in sodium alginate beads. Two chemicals of interest were selected for investigation, namely diazinon (an insecticide) and propineb (a fungicide), and were detected at low nanomolar levels on this platform through the monitoring of changes in membrane potential. Of particular interest in this study was the ability of the sensor format to subsequently differentiate between organic ($n = 5$) and pesticide-treated ($n = 8$) tomato samples that had 14 detectable pesticide residues, including diazinon and thiabendazole. The principle behind this particular assay was the monitoring of cytosolic calcium accumulation in the neuroblastoma cells, with pesticide residues inducing cell membrane depolarisation. This interesting observation demonstrates the potential of using biosensors to differentiate between organic and non-organic agricultural produce, which is of particular interest to the consumer. Furthermore, with the recent trends in biosensor miniaturisation, it is likely that future sensors will permit this differentiation to be performed 'on-site'.

Many other examples demonstrate the use of electrochemical biosensors for monitoring the presence of indicator molecules that are representative of contamination. In an early example, Voss and Galensa (2000) used an electrochemical biosensor to monitor the presence and concentration of amino acids in fruit juice. Amino acids were separated on a lithium cation-exchange HPLC column, and an amperometric platform was subsequently used to monitor the production of H_2O_2. This assay could detect amino acid concentrations ranging from 0.1 mg/mL to 5 mg/mL (D-proline and D-methionine to L-alanine, respectively) in a range of different analytical samples, including fruit juice, wine and beer. D-alanine was detected at a concentration of 0.5 mg/mL, and the authors suggested that the presence of this amino acid was a result of bacterial contamination. Kriz et al. (2002) used a SIRE (sensors based on injection of the recognition element)-based biosensor to monitor L-lactate content in baby food and tomato paste, whereby a small amount of enzyme (lactate oxidase) was injected into an internal delivery flow system and was held in direct spatial contact with an amperometric transducer by a semi-permeable membrane. Measurements were determined by the enzymatic conversion of L-lactate to pyruvate and H_2O_2, and the range of detection of L-lactate was between 0.10 and 2.51 mM. Here, all assay measurements were compared to an established spectrophotometric assay, with the contributors stating that the biosensor method employed during this analysis had a distinct advantage, as the measurement could be performed in less than 3 minutes (as opposed to 30–35 minutes for spectrophotometry-based analysis).

Additional examples of electrochemical sensor-based detection of contaminants include the development of an immunosensor for the detection of 2,4-D based on electrochemical impedance spectroscopy (Navrátilová and Skádal 2004) and, more recently, a sensor implementing a molecularly-imprinted conducting polymer, namely poly(3,4-ethylenedioxythiopene-co-thiopene-acetic acid), for the detection of atrazine (Pardieu et al. 2009). These platforms had sensitivities of 45 nmol/L and 10^{-7} mol/L for 2,4-D and atrazine, respectively, and demonstrate the efficacy of using electrochemical detection as an alternative to optical platforms, such as Biacore, for quality determination.

In recent years, there is a steadily increasing trend for the development of biosensors in an array format, where multiple analytes can be measured simultaneously on a single device. Examples of optical platforms that permit this analysis have been discussed earlier by Herranz et al. (2008) and Gao et al. (2009), and many electrochemical platforms are also available. An enzyme-based three-electrode biosensor for detecting the presence of markers of maturity and quality in tropical fruits was developed by Jawaheer et al. (2003). The assay was developed to quantifiably determine the presence of β-D-glucose, total D-glucose, sucrose and ascorbic acid in pineapples, mangos and papaya fruit. These markers are indicative of maturity and quality in selected fruit products and were detected in pectin (a natural polysaccharide present in plant cells) extracted from these samples. A fabrication format was developed that permitted the integration of the individual sensors into a multi-sensor

array, and analytes were measured in this matrix to enhance the enzymatic responses over analyte ranges of 0–7 mM. Interferences normally related to electrochemically active compounds present in fruits were minimised by including a membrane made out of cellulose acetate.

Electrochemical assay formats may be further enhanced by electrochemiluminescence (ECL). ECL reactions are of interest because of their versatility for a range of different types of immunoassay. The principle of ECL is the co-oxidation of luminol and a substrate (called an enhancer) by H_2O_2 in the presence of the enzyme horseradish peroxidase (HRP). The resulting amperometric signal is detected by the transducer and a quantifiable electrical signal is generated. ECL as a detection system has advantages over other methods, including high sensitivity and a reduced assay time. In experiments carried out by Rubtsova et al. (1998), specific antibodies against atrazine were covalently immobilised on photo-activated nylon. A chemiluminescence-based assay was subsequently used to measure 2,4-D with a detection limit of 0.2 μg/L.

Portable electrochemical biosensors are also applicable for the detection of herbicide and pesticide residues. A portable and disposable immunomembrane-based electrochemical biosensor was developed for the detection of picloram in spiked lettuce, rice and water samples, and the latter extracted from paddy fields. The competitive assay format developed here by Tang et al. (2008) utilised a polyclonal anti-picloram antibody, purified from serum extracted from immunised rabbits, and had a sensitivity of 5 ng/mL.

ALTERNATIVE BIOSENSOR FORMATS

Other types of biosensors have also been used for post-harvest analysis. Pogačnik and Franko (2003) developed a photothermal biosensor to measure organophosphate and carbamate compounds in salads, lettuce and onions. This approach used thermal lens spectrometry, a technique that depends upon the adsorption of optical radiation in the sample generating heat. This introduces a change in the RI, and, through this analysis, concentrations can be determined. Paraoxon was detected in all of the samples tested by this protocol. Recently, a piezoelectric antibody-based sensor for the detection of pesticide residues in fruit juice matrices was described by March et al. (2009). Piezoelectric, or mass-based, sensors operate on the principle that a biorecognition event, such as the interaction between an antibody and an agricultural contaminant, results in a change

in mass. This is conducive to a change in, for example, resonance frequency that can readily be detected by the end-user. Piezoelectric sensors typically use quartz crystals as transducers, and are a cost-effective alternative to optical sensors, which are often expensive (Byrne et al. 2009, Conroy et al. 2009). The immunosensor described by March et al. was based on the implementation of a quartz-crystal microbalance for detecting carbaryl and 3,5,6-trichloro-2-pyridinol (TCP) residues. Here, a rapid (20 minute) inhibition assay format was adopted, using antigen-specific monoclonal antibodies for biorecognition, and the piezoelectric sensor had good detection limits for carbaryl (11 μg/L) and TCP (7 μg/L) in spiked fruit juice samples, although the authors suggested that assay sensitivity could be improved by incorporating crystals with enhanced resonance frequencies. However, this example does emphasise the efficiency of using biosensors for detecting analytes of interest in complex and coloured sample matrices without the need for sample pre-preparation, which significantly reduces analysis times.

PATHOGENS

BACTERIAL PATHOGENS

Several bacterial strains are of great significance for the food and horticultural industries, including *L. monocytogenes*, *S. typhimurium* and *E. coli* O157:H7, and Table 45.6 show some of the earlier examples of using SPR instruments to detect the presence of bacterial contaminants in food. The bacterial strain *E. coli* 0157:H7 is a major pathogen of interest in fruit and vegetables, as it causes severe illness and can be fatal in the infants, the elderly and the immunocompromised (Byrne et al. 2009). Hence, the detection and enumeration of this and other bacterial pathogens are absolute requirements for the food industry. A disposable conductometric electrochemical immunosensor, based on a lateral flow strip connected to an ohmmeter, was described by Muhammad-Tahir and Alocilja (2004). Anti-*E. coli* O157:H7 antibodies, labelled with polyaniline (PANI), were immobilised onto the nitrocellulose strip and a sample was allowed to migrate up the strip. PANI is an excellent conducting polymer frequently selected for use in chemical sensor platforms. A drop in resistance, proportional to the concentration of *E. coli* 0157:H7 cells binding to the antibodies, indicated a decrease in the electron transfer from the PANI-conjugated antibody.

L. monocytogenes is a highly infectious pathogen that has very serious implications if present in food or food products due to the

Table 45.6. Examples of Surface Plasmon Resonance-Based Analysis of Bacterial Pathogens

Analyte	Limit of Detection	Reference
Salmonella enteritidis, *Listeria monocytogenes*	106 cells/mL	Koubová et al. 2001.

associated risk of fatality (Hearty et al. 2006). While the natural ecosystem of this bacterial strain includes soil, water, plant material and decaying plant detritus (Suihko et al. 2002), numerous foods, such as raw vegetables, fruits, and horticultural samples, are also prone to infection. Furthermore, the psychrophilic nature of this strain, conferring the ability to grow at refrigeration temperatures, and the ability of this bacterium to withstand high salt concentrations and tolerate a wide pH range suggest that contamination of foodstuffs such as coleslaw is a frequent occurrence. Leonard et al. (2005) devised a rapid SPR-based immunosensor assay for the detection of *L. monocytogenes*, which incorporated a polyclonal antibody specific for internalins. Internalin B (InlB), a protein on the surface of *L. monocytogenes*, participates with Internalin A (InlA) in the invasion of mammalian cells. In this assay format, the antibody was immobilised on a CM5 sensor chip and varying concentrations of cells were then injected over the surface. A detection limit level of less than 2×10^5 cells/mL of sample was reported. Hearty et al. (2006) generated a monoclonal antibody that specifically interacted with the InlA surface protein, and demonstrated the efficacy of this antibody by developing a Biacore-based assay capable of detecting 1×10^7 cells/mL. Finally, Tully et al. (2006) described the use of quantum dot-labelled antibodies, specific for InlA, for the immunostaining of *L. monocytogenes* cells, and demonstrated that these have major potential for use with fluorescence-based sensor formats. These three examples demonstrate the efficacy of detecting bacterial pathogens through the identification of cell surface epitopes and subsequent generation of antibodies. Bacterial cells, in particular, present an array of different antigenic determinants, including capsular, flagellar and surface antigens. While carbohydrate elements may also, in theory, be targeted, these typically have lower immunogenic potential than their proteinaceous counterparts, and therefore are rarely used for biorecognition.

Many of the more recent examples of biosensor-based bacterial pathogen detection have focused on the use of electrochemical platforms, including impedimetric assays. Tully et al. (2008) described an impedance-based assay for the analysis of the *L. monocytogenes* InB protein, which used a leporine host-derived polyclonal antibody as a bioligand. The assay format developed, which used planar screen-printed carbon electrodes modified with PANI for antibody capture, had an excellent LOD for InlB (4.1 pg/mL). Additional electrochemical platforms have also been developed for the detection of *S. typhimurium*, a pathogen typically transmitted to human hosts through the ingestion of contaminated animal produce, such as meat, eggs or milk. Nandakumar et al. (2008) devised an antibody-based impedimetric assay capable of detecting 500 colony forming unit (CFU)/mL of *S. typhimurium* in less than 10 minutes. Interestingly, the authors suggested that the developed methodology would be of particular use in portable pathogen detectors, due to the relatively low complexity of the sensor format and the necessity for a small number of data samples (30) to provide accurate pathogen detection.

Biosensors are particularly useful for the rapid detection of analytes of interest in complex sample matrices, and this also applies to the detection of bacterial pathogens where additional methodologies may be used in conjunction with immunosensing for pathogen retrieval. Immunomagnetic separation (IMS) may be applied to initially pre-concentrate bacterial cells from a food sample prior to biosensor-based analysis (Byrne et al. 2009) and, as with all immunodetection-based strategies, the efficacy of this approach is dependent on the quality of the antibody that is selected for biorecognition. Liébana et al. (2009) used a combination of IMS and magnetic electrode-based electrochemical biosensing for detecting *S. typhimurium* cells in milk, with the antibody capable of selectively differentiating between target and *E. coli* cells in this matrix. Detection was verified through the introduction of a second HRP-labelled anti-*Salmonella* antibody, thereby creating a sandwich assay format on the sensor surface that could be completed in less than one hour. Interestingly, the sensitivity of this assay was influenced by the nature of the samples selected for analysis. When *S. typhimurium* cells were propagated in Luria Bertani (LB) medium, the LOD was 5×10^3 CFU/mL. In spiked milk samples diluted tenfold in LB medium, the sensitivity was 7.5×10^3 CFU/mL. However, when the milk was pre-enriched for six and eight hours, the limits of detection could be significantly reduced to 1.4 CFU/mL and 0.1 CFU/mL, respectively, suggesting that sample preparation has a significant impact on assay sensitivity.

Salam and Tothill (2009) also developed an electrochemical immunosensor for *S. typhimurium* detection that was applied for the analysis of chicken breast samples. The assay format consisted of a murine monoclonal antibody captured on a screen-printed gold electrode via amine coupling. Similarly to the example described above by Liébana et al. (2009), a secondary HRP-labelled polyclonal antibody was selected for enhancing specificity. The assay format permitted rapid cross-reactivity analysis to be performed with additional bacterial strains, including *Staphylococcus aureus*, *Pseudomonas* spp. and *Klebsiella pneumonia* (all at a concentration of 1×10^9 CFU/mL). This is an important consideration for pathogen detection, and the ability to develop a species-specific immunoassay and subsequently, screen for non-specific binding to additional bacterial strains/pathogens is essential.

Liao and Ho (2009) describe a novel electrochemical sensor for the detection of *E. coli* O157:H7. Instead of selecting an epitope on the bacterial cell for immunorecognition, a gene encoding an enzyme that participates in O-antigen assembly (*rfb*E) was targeted by a single-stranded DNA probe, and the resultant assay had excellent sensitivity (0.75 amol) for the target gene. In another excellent example, Koo et al. (2009) developed an 'antibody-free' biosensor platform for the detection of *L. monocytogenes*. Here, the biomolecular interaction between the *Listeria* adhesion protein (LAP, also referred to as alcohol acetaldehyde dehydrogenase) and biotin-tagged heat shock protein 60 (HSP60) was used to facilitate the detection of this opportunistic pathogen in a matrix containing additional pathogenic bacterial strains, including *Bacillus cereus* and *Proteus vulgaris*. Of particular interest in this study was the observation that the efficiency of detection observed through the use of the HSP biorecognition element was over 80-fold higher than for an anti-*L. monocytogenes* monoclonal antibody previously developed in the same laboratory.

FUNGAL PATHOGENS

The sensitive detection of fungal strains is also of great importance, due to their association with crop spoilage and inherent ability to act as human pathogens. A key consideration when analysing fungal cells and spores by optical biosensing relates to the fact that they are significantly larger than their bacterial counterparts. Fungal spores are often over 40 μM in diameter, which complicates analysis in platforms, such as Biacore, where system blockages may result from their direct injection. Hence, it is possible to utilise modified assay formats, such as a subtraction inhibition assay (SIA), for the detection of these large fungal spores (Byrne et al. 2009). The principle behind the SIA involves the pre-incubation of antigen with a target-specific antibody. Unbound antibody is subsequently retained (e.g. by centrifugation or by filtration) and enumerated by capturing on a biosensor surface immobilised with an antibody-specific capture immunoglobulin. The observed response is inversely proportional to the amount of pathogen present in the original sample or culture, and the major benefit of the SIA assay format is that the system is not exposed to potentially harmful pathogens. This Biacore SIA format is also applicable for the monitoring of bacterial cells, including *L. monocytogenes* (Leonard et al. 2004).

SIA-based detection of fungal pathogens was demonstrated by Skottrup et al. (2007a), who pre-incubated a murine monoclonal antibody with sporangia of the fungal strain *Phytophthora infestans* and used a centrifugation-based protocol for separating free and bound antibodies. Free immunoglobulin was subsequently passed over a Biacore CM5 surface containing immobilised goat anti-mouse polyclonal antibody, which was used to quantitate free antibody over a pre-determined dilution series. The LOD was 2.2×10^6 sporangia/mL, and no cross-reactivity was seen when other fungal strains, such as *Botrytis cinerea* and *Melampsora euphorbiae* were assayed in parallel. A similar assay was also selected for detecting spores of *Puccinia striiformis*, a well-characterised plant pathogen. Here, a polyclonal rabbit anti-mouse IgM antibody was used for the capture of a monoclonal antibody (IgM), whose production was elicited in a murine host immunised with whole urediniospores. The resultant assay took approximately 45 minutes to complete and permitted the detection of 3.1×10^5 urediniospores/mL (Skottrup et al. 2007b). These two important examples demonstrate the applicability of using biosensor-based analysis for the detection of fungal spores, which is another key consideration for the evaluation of quality.

TOXINS

MYCOTOXINS

Mycotoxins are toxic compounds that are synthesised as secondary metabolites by fungal strains. For example, the fungus *Fusarium moniliforme* produces the carcinogenic mycotoxin, fumonisin B_1. Mullett et al. (1998) developed a rapid (approximately 10 minutes) SPR method to detect this mycotoxin in spiked samples. Here, polyclonal fumonisin B_1-specific antiserum (2 mg/mL) was diluted (1:5,000, 1:10,000, 1:1,500 and

1:2,000) and immobilised onto gold layers. Next, fumonisin B_1, in concentrations of 0.0–100 μg/mL, was subsequently passed over each surface, prior to measuring the change in SPR. Their assay had a detection limit of 50 ng/mL. This research group state that the 'lab-made' SPR device used in their research could be implemented as an early stage method in the screening of large numbers of potentially contaminated food samples. Positive samples could then be analysed further by more sensitive methods of analysis, such as liquid chromatography or electrospray ionisation mass spectrometry (Hartl and Humpf 1999). More recently, van der Gaag et al. (2003) developed a biosensor-based assay capable of detecting fumonisin B_1 and three other analytes, namely zearalenone, ochratoxin A and aflatoxin B_1.

The monitoring of the presence of aflatoxins, which are naturally occurring mycotoxins produced by several strains of *Aspergillus* spp., in fruit, vegetable and food produce, is also of critical significance. Produce prone to contamination includes nuts (almonds, walnuts), cereals (rice, wheat, maize) and oilseeds (soybean and peanuts). Aflatoxin monitoring is also important as consumption of infected produce is implicated in carcinoma of the liver (Bhatnagar et al. 2002, Bennett and Klich 2003). While approximately 16 structurally diverse aflatoxins have been reported, aflatoxins B_1, B_2, G_1 and G_2 and M represent the greatest danger to human health (Keller et al. 2005). Many of these compounds may be generated in *Aspergillus parasiticus*, while *Aspergillus flavus* can synthesise aflatoxins B_1 and B_2 (Yu et al. 2004).

Several biosensor-based platforms have been developed to permit the detection of trace levels of different aflatoxins (Lacy et al. 2006). Daly et al. (2000) used a rabbit-derived polyclonal antibody to detect AFB_1, which was conjugated to BSA and immobilised onto a CM5 Biacore chip. A competition assay between free and bound AFB_1 had a linear range of detection (3–98 ng/mL). Daly et al. (2002) subsequently generated murine scFvs against AFB_1 by using a phage display format and incorporated these antibodies into a Biacore-based inhibition assay. Dunne et al. (2005) developed a unique SPR-based inhibition assay that incorporated monomeric and dimeric scFv antibody fragments that could detect AFB_1. Monomeric scFvs could detect between 390 and 12,000 ppb, while the dimeric scFv was more sensitive, detecting between 190 and 24,000 ppb.

Several other research groups have developed similar rapid analytical biosensor-based platforms for aflatoxin detection. Sapsford et al. (2006) developed an indirect competitive immunoassay on a fluorescence-based biosensor that permitted rapid detection of AFB_1 in spiked corn (cornflakes, cornmeal) and nut (peanuts, peanut butter) products. Mouse monoclonal antibodies were labeled with the fluorescent dye CY5, with detectable signals inversely proportional to the concentration of AFB_1 present. Limits of detection for nut and corn products were 0.6–1.4 ng/g and 1.5–5.1 ng/g, respectively. Adanyi et al. (2007) also recently described a unique protocol for permitting aflatoxin detection by using optical wavelength lightmode spectroscopy (abbreviated to OWLS). Integrated optical wavelength sensors were selected for use in this experiment with the detection range for a competitive assay being between 0.5 and 10 ng/mL. An indirect screening protocol was subsequently applied to wheat and

barley that permitted the detection of AFB_1 and ochratoxin A. A more recent example of biosensor-based detection of the latter toxin is provided by Yuan et al. (2009), who selected a Biacore Q-based platform for their analysis. In this study, a murine-derived monoclonal antibody was used for the detection of ochratoxin residues in spiked cereal, beverages, juices (apple and grape) and wine samples in a competition assay format. Sensitivity was significantly enhanced by using gold nanoparticles.

Not all biosensor-based technologies for the evaluation of quality use antibodies for biorecognition, and this is also applicable to the detection of aflatoxins. An example is the development of an enzyme-based SPR assay for the detection of AFB_1 and AFG_1. The principle behind this assay was the ability of these aflatoxins to bind to porcine neutrophil elastase. The efficacy of using this approach was demonstrated by the excellent sensitivity that was observed (low ppb for both analytes), which demonstrates the potential of using enzymatic biosensors as alternatives to immunosensors for detection purposes (Cuccioloni et al. 2008).

WATER AND MARINE TOXINS

Marine toxins pose a considerable threat to human health because of their potential to cause respiratory, neurological and gastrointestinal problems, including mortalities at very low toxin concentrations. This is primarily linked to the consumption of contaminated shellfish meat. Hence, a number of countries have established regulations and specific concentration limits to control the acceptable levels of these phycotoxins in seafood (FAO 2004).

Phycotoxins include a variety of toxins from different phytoplankton groups. They vary widely in their physical properties, chemical structure and toxic mechanisms. The type of poisoning and, therefore, the phycotoxin groups are classified according to the associated symptoms: paralytic shellfish poisoning (PSP), neurotoxic shellfish poisoning, amnesic shellfish poisoning (ASP), diarrheic shellfish poisoning (DSP) and azaspiracid shellfish poisoning associated with shellfish; and ciguatera poisoning associated with finfish. ASP results from contamination with the amino acid molecule domoic acid and its derivatives. Domoic acid is a potent kainoid, neuroexcitatory toxin produced by the marine diatom *Pseudo-nitzschia pungens* (Pan et al. 2001). Many species of shellfish bioaccumulate domoic acid through the consumption of toxin-containing phytoplankton. Furthermore, shellfish known to have been contaminated with domoic acid include anchovies, crabs, mussels, clams, scallops, gastropods, mackerel and oysters. It was shown that the first gastrointestinal (nausea, vomiting, diarrhoea and abdominal cramps) and neurological symptoms (memory loss) will appear 15 minutes post-consumption of contaminated shellfish. Vision problems may also occur, including diplopia, disconjugate and ophthalmoplegia. Severe intoxication will cause significant neurological issues, including confusion and seizures, sometimes leading to coma and death.

SPR has been applied for the detection of domoic acid in an indirect competitive immunosensor format (Yu et al. 2005). Domoic acid was covalently linked onto a mixed self-assembled monolayer (SAM)-modified SPR chip and competition occurred between free domoic acid and anti-domoic acid monoclonal antibodies in solution. The detection limit was 0.1 ng/mL, which was lower than what was initially obtained when normal colorimetric ELISA analysis was performed. This was due to the lack of non-specific antibody adsorption on the SAM and the high sensitivity of the SPR instrument. Stevens et al. (2007) subsequently developed a portable six-channel SPR system for domoic acid detection in clam extracts with a LOD of 3 ng/mL and a quantitative detection range of 4–60 ng/mL. The portability of this biosensor is a key advantage over other SPR-based sensors, as both researchers and governmental shellfish monitoring programmes have highlighted the need for rapid in situ methods for monitoring biotoxin contamination (Kröger et al. 2002).

DSP results from the consumption of molluscs contaminated with the polycyclic ether toxins okadaic acid (OA), dinophysis toxin-1 (DTX1) and pectenotoxins (PTX). Yessotoxin (YTX) is also classified under this grouping as it was first isolated in 1987 from scallops associated with a DSP poisoning event, although the pharmacological activity of YTXs is different to that of DSP toxins (Bowden 2006). OA, DTX and PTX are all produced by dinoflagellates belonging to the *Dinophysis* and *Prorocentrum* species, whereas YTXs are produced by *Protoceratium reticulatum* (Satake et al. 1999). The known marine organisms susceptible to infection by *Dinophysis* and *Prorocentrum* include clams, mussels, oysters and scallops. The main symptom associated with DSP poisoning is diarrhoea, but other symptoms such as abdominal pain, nausea and vomiting may also occur. Hospitalisation is not normally required, and no human deaths have been documented to date.

Llamas et al. (2007) developed a unique SPR-based immunosensor for the detection of OA in shellfish extracts. They utilised a polyclonal antibody generated through repeated immunisation of an OA-bovine thyroglobulin (BTG) conjugate into a rabbit host and an amine sensor chip surface functionalised with an OA derivative, OA-*N*-hydroxysuccinimide. In this competition assay, 20 mussel samples, negative for OA, were spiked with 160 ng/g of OA. When compared to LC-MS, the immunosensor demonstrated a slight overestimation of OA. Furthermore, the polyclonal antibody was found to have 40% cross-reactivity with DTX-1, but when applied to a matrix environment no cross-reactivity was observed. Subsequently, a monoclonal antibody was developed against an OA-BTG conjugate (Stewart et al. 2009) that showed a cross-reactivity profile for both DTX-1 and DTX-2 that corresponded with the toxin potency of all the OA toxins. The antibody was selected using a novel approach in which hybridoma screening was carried out in an ELISA competition format, a direct ELISA format and a SPR biosensor format, using an OA-immobilised CM5 sensor chip.

PSP causes a significant risk to public health due to its high mortality rate and considerable economic damage. PSPs are water soluble, thermostable, tetrehydropurine molecules, which are subdivided into four structural categories; carbamates, *N*-sulfo-carbamoyls, decarbamoyls and deoxydecarbamoyls. The main phycotoxins associated with PSP include the neurotoxins, gonyatoxin (GTX) and saxitoxin (STX). The carbamate STX is

the most toxic and over 20 different analogues have been described (Fusetani and Kern 2009), with a range of associated toxicity levels. PSPs are known to be produced by *Alexandrium, Gymnodinium* and *Pyrodinium* species. Infected organisms can include clams, crabs, cockles, cods, gastropods, herrings, lobsters, mackerel, mussels, oysters, pufferfish and scallops. Symptoms can be neurological and, less frequently, gastrointestinal, including nausea, vomiting and diarrhoea. These symptoms can appear from 15 minutes to 10 hours after ingestion of contaminated shellfish, any may also be associated with the onset of a tingling, a prickly feeling in the toes and fingertips, a burning sensation of the lips and skin, dizziness, numbness in the mouth and extremities, headache, ataxia and fever. Individuals may also experience a feeling of calmness and serenity. Severe poisoning can lead to lack of coordination and respiratory distress that can lead to death within 2–25 hours of intoxication.

Fonfría et al. (2007) developed a SPR inhibition assay using an anti-GTX2/3 antibody and a STX-immobilised CM5 Biacore surface. Here, STX in solution was detected by competition for binding to the anti-GTX2/3 antibody. The biosensor detected a number of different saxitoxin analogues, including dcSTX, GTX2/3, dcGTX2/3, GTX5 and C1/2 (with slightly higher sensitivity than STX). Significantly, the antibody had low cross-reactivity for neoSTX, GTX1/4 or decarbamoyl neosaxitoxin. The biosensor platform was subsequently shown to be effective in a number of different shellfish matrices, including mussels, clams, cockles, scallops and oysters, with a detection limit between 2 and 50 ng/mL observed. More recently, Taylor et al. (2008) devised a novel SPR immunosensor for the low molecular weight toxin, tetrodotoxin (TTX), using a polyclonal anti-TTX antibody as a biorecognition element. TTX was chemically immobilised on a gold film with a mixed SAM, which reduced non-specific binding at the surface. The inhibitory concentration causing 20% displacement (IC_{20}) for the assay was approximately 0.3 ng/mL, and the corresponding concentration for 50% displacement (IC_{50}) was approximately 6 ng/mL. In summary, these examples clearly demonstrate how biosensors can be used to monitor potentially fatal contaminants in water and marine life, which has a direct impact on the food industry.

LEGISLATION

In this chapter, a variety of different biosensor-based platforms used to detect a range of different molecules such as pesticides, herbicides, mycotoxins and phycotoxins are described. It is important to consider the legislation associated with the monitoring of quality. The Food and Agriculture Organisation of the United Nations (FAOSTAT) (http://faostat.fao.org/) is an international body whose overall aim is to protect the health of consumers. FAOSTAT has an online database (The Codex Alimentarius: Pesticide Residues in Food Maximum Residue Limits; see 'Websites of Interest'), which details the MRLs for pesticides in commodities such as fruit and vegetables. The establishment of a MRL (usually expressed as mg/kg) is dependent on good agricultural practice for pesticides. This relates to where the highest detectable residues anticipated (when a pesticide-containing product is applied to a commodity to remove con-

taminants) are intended to be toxicologically acceptable. Under these arrangements, the important point is that residue levels do not pose unacceptable risks for consumers by being present in values that exceed these levels.

Similar legislation exists within the European Union (EU). Within the EU Directive (91/414/EEC), the Plant Protection Products Directive ('The Authorisations Directive': 1991) was proposed with the aim of harmonising the overall arrangements for authorisation of plant protection products within the EU. However, legislation relating to MRLs of pesticides in cereals, fruit, vegetables, foods of animal origin and feeding stuffs was substantially amended several times since this legislation was developed. A single act has replaced the amended original Directive Regulation (EC) No. 396/2005. This establishes maximum levels of pesticide residues permitted in or on food and feed of plant and animal origin. These MRLs include levels that are specific to particular foodstuffs that are intended for human or animal consumption, and a general limit that applies where no specific MRL has been established.

As infants have developing immune systems, fruit and vegetable-based baby foods need to be rigorously monitored, as the presence of low concentrations of pesticides could be of significance. The EU has set an MRL for any given pesticide in infant foods of a concentration not exceeding 10 μg/mL. This information is very significant for the use and future applications of biosensor-based detection methods.

The EU has established an upper safe limit of 20 mg/kg for total ASP toxin content in the edible part of the mollusc (EEC 1991), with HLPC selected as a reference method. The European Commission have set tolerable levels for OA, DTXs and PTXs present in edible tissues at 160 μg OA equivalent/kg shellfish and a maximal level of YTXs of 1 mg YTX equivalent/kg shellfish (European Commission Decision 2002). The mouse or rat bioassay is the reference method for DSP detection. The EU directive 91/492/EEC allows a maximum level of PSP toxin of 80 μg STX eq/100g shellfish meat. The European Commission also decided in 2002 (2002/226/EC) to allow a conditional harvesting of scallops with a concentration of domoic acid (DA) in the whole body exceeding 20 mg/kg but lower than 250 mg/kg, based on the limit of ASP, imparted by Council Directive 91/492/EEC (1991). More recently (2009), the European Food Safety Authority (EFSA) recommended that it was safe to consume shellfish containing less than 4.5 mg domoic acid/kg, so as not to exceed the acute reference dose of 30 μg DA/kg body weight (equivalent to 1.8 mg DA per portion for a 60 kg adult) (EFSA 2009a, EFSA 2009b).

CONCLUSION

This chapter has provided a concise review of how biosensors may be applied to monitoring the quality of fruit and vegetable produce, and also for the detection of pathogens (bacterial and fungal) and associated toxins. Examples are given where such applications have been successfully employed, while recent developments in the area have focused on the development of low and high-density arrays capable of multiple analyte monitoring and portable or disposable platforms for in situ monitoring. With

the advent of such technology in a user-friendly format, the scope for analysis will be greatly expanded and simplified, leading to a very significant improvement in food quality analysis.

Glossary

This illustrates some of the compounds described in the text that are of relevance to the food industry. These are listed below in order of their appearance in the text.

SMALL MOLECULAR WEIGHT CONTAMINANTS
Fludioxonil
Atrazine
General carbamate structure
Chlorophenol red
2-(4-Thiazolyl)benzimidazole
2,4-Dichlorophenoxyacetic acid
2,4,5-Trichlorophenoxyacetic acid (2,4,5-T)
Isoproturon
Simazine
Propazine
17-β-estradiol
Nonylphenol
Ferrocene
Parathion
Carbofuran
Carbaryl
Chlorpyrifos
Pirimiphos-methyl
Diazinon
Propineb
Thiabenzadole
D-glucose
3,5,6-Trichloro-2-pyridinol

Sucrose

POLYKETIDES
Tylosin
Ascorbic acid
MYCOTOXINS

Picloram
Fumonisin B$_1$

AFLATOXINS
Paraoxon
Aflatoxin B$_1$
PHYCOTOXINS
Aflatoxin B₂

Aflatoxin G₁
Aflatoxin G₂
Aflatoxin M₁
Ochratoxin
Okadaic acid

Saxitoxin

Domoic acid

Index
